Abstract. In *d*-SCATTERED SET we are given an (edge-weighted) graph and are asked to select at least k vertices, so that the distance between any pair is at least d, thus generalizing INDEPENDENT SET. We provide upper and lower bounds on the complexity of this problem with respect to various standard graph parameters. In particular, we show the following:

- For any $d \ge 2$, an $O^*(d^{tw})$ -time algorithm, where tw is the treewidth of the input graph.
- A tight SETH-based lower bound matching this algorithm's performance. These generalize known results for INDEPENDENT SET.
- d-SCATTERED SET is W[1]-hard parameterized by vertex cover (for edge-weighted graphs), or feedback vertex set (for unweighted graphs), even if k is an additional parameter.
- A single-exponential algorithm parameterized by vertex cover for unweighted graphs, complementing the above-mentioned hardness.
- A 2^{O(td²)}-time algorithm parameterized by tree-depth (td), as well as a matching ETH-based lower bound, both for unweighted graphs.

We complement these mostly negative results by providing an *FPT* approximation scheme parameterized by treewidth. In particular, we give an algorithm which, for any error parameter $\epsilon > 0$, runs in time $O^*((\text{tw}/\epsilon)^{O(\text{tw})})$ and returns a $d/(1 + \epsilon)$ -scattered set of size k, if a d-scattered set of the same size exists.

1 Introduction

In this paper we study the *d*-SCATTERED SET problem: given graph G = (V, E)and a metric weight function $w : E \mapsto \mathbb{N}^+$ that gives the length of each edge, we are asked if there exists a set K of at least k selections from V, such that the distance between any pair $v, u \in K$ is at least $d(v, u) \ge d$, where d(v, u) denotes the shortest-path distance from v to u under weight function w. If w assigns weight 1 to all edges, the variant is called *unweighted*.

The problem can already be seen to be hard, as it generalizes INDEPENDENT SET (for d = 2), even to approximate (under standard complexity assumptions), i.e. the optimal k cannot be approximated to $n^{1-\epsilon}$ in polynomial time [18], while an alternative name is DISTANCE-d INDEPENDENT SET [13,28,12]. This hardness prompts the analysis of the problem when the input graph is of restricted structure, our aim being to provide a comprehensive account of the complexity of d-SCATTERED SET through various upper and lower bound results. Our viewpoint is parameterized: we consider the well-known structural parameters treewidth \mathbf{tw} , tree-depth \mathbf{td} , vertex cover number \mathbf{vc} and feedback vertex set number \mathbf{fvs} , that comprehensively express the intended restrictions on the input graph's structure (as they range in size and applicability), while we examine both the edge-weighted and unweighted variants of the problem.

Our contribution: First, in Section 3 we present a lower bound of $(d - \epsilon)^{\text{tw}} \cdot n^{O(1)}$ on the complexity of any algorithm solving *d*-SCATTERED SET parameterized by tw, based on the Strong Exponential Time Hypothesis (SETH [19,20]). This result can be seen as a non-trivial extension of the bound of $(2 - \epsilon)^{\text{tw}} \cdot n^{O(1)}$ for INDEPENDENT SET ([25]) for larger values of *d*, for which the construction is required to be much more compact in terms of encoded information per unit of treewidth.

In Section 4 we provide a dynamic programming algorithm of running time $O^*(d^{tw})$, matching this lower bound, over a given tree decomposition of width tw. The algorithm actually solves the counting version of *d*-SCATTERED SET, making use of standard techniques (dynamic programming on tree decompositions), with an application of the fast subset convolution technique of [2] (or *state changes* [7,31]) to bring the running time down to match the size of the dynamic programming tables.

Having thus identified the complexity of the problem with respect to tw, we next focus on the more restrictive parameters vc and fvs and we show in Section 5 that the edge-weighted *d*-SCATTERED SET problem parameterized by vc + k is W[1]-hard. If, on the other hand, all edge-weights are set to 1, then *d*-SCATTERED SET (the unweighted variant) parameterized by fvs + k is W[1]-hard. Our reductions also imply lower bounds based on the Exponential Time Hypothesis (ETH [19,20]), yet we do not believe these to be tight, due to the quadratic increase in parameter size (as the construction's focus lies on the edges). One observation that can be made is that there are few cases where we can expect to obtain an FPT algorithm for the problem without bounding the value of *d*.

We complement these results with a single-exponential algorithm for the unweighted variant, of running time $O^*(3^{vc})$ for the case of even d, while for odd d the running time is $O^*(4^{vc})$. The algorithm is based on defining a sub-problem based on a variant of SET PACKING that we solve via dynamic programming. The difference in running times, depending on the parity of d, is due to the number of possible situations for a vertex with respect to potential candidates for selection.

Further, for the unweighted variant we also show in Section 7 the existence of an algorithm parameterized by td of running time $O^*(2^{O(td^2)})$, as well as a matching ETH-based lower bound. The upper bound follows from known connections between the tree-depth of a graph and its diameter, while the lower bound comes from a reduction from 3-SAT.

Finally, we turn again to tw in Section 8 and we present a fixed-parametertractable approximation scheme (FPT-AS) of running time $O^*((tw/\epsilon)^{O(tw)})$ that finds a $d/(1+\epsilon)$ -scattered set of size k, if a d-scattered set of the same size exists. The algorithm is based on a rounding technique introduced in [24] and can be much faster than any exact algorithm for the problem (for large d, i.e. $d \ge O(\log n)$), even for the unweighted case and more restricted parameters. Figure 1 illustrates the relationships between considered parameters and summarizes our results, while we refer the reader to the full version [22] for all omitted definitions, constructions and proofs (also in Appendices A and B).

Related work: Our work can be considered as a continuation of the investigations in [21], where the (k, r)-CENTER problem is similarly studied with respect to several well-known structural parameters and a number of fine-grained upper/lower bounds is presented, while some of the techniques employed for our SETH lower bound are also present in [8].

The SETH-based lower bound of $(2 - \epsilon)^{\text{tw}} \cdot n^{O(1)}$ on the running time of any algorithm for INDEPENDENT SET parameterized by two comes from [25]. For d-SCATTERED SET, Halldórsson et al. [17] showed a tight inapproximability ratio of $n^{1-\epsilon}$ for even d and $n^{1/2-\epsilon}$ for odd d, while Eto et al. [13] showed that on r-regular graphs the problem is APX-hard for $r, d \geq 3$, while also providing polynomial-time $O(r^{d-1})$ -approximations and a polynomial-time approximation scheme (PTAS) for planar graphs. For a class of graphs with at most a polynomial (in n) number of minimal separators, d-SCATTERED SET can be solved in polynomial time for even d, while it remains NP-hard on chordal graphs (contained in the class) and any odd $d \ge 3$ [28]. It remains NP-hard even for planar bipartite graphs of maximum degree 3, while a 1.875-approximation is available on cubic graphs [14] Several hardness results for planar and chordal (bipartite) graphs can be found in [12], while [16] shows the problem admits an EPTAS on (apex)-minor-free graphs, based on the theory of bidimensionality. Finally, on a related result, Marx and Pilipczuk recently offered an $n^{O(\sqrt{k})}$ -time algorithm for planar graphs, making use of Voronoi diagrams and based on ideas previously used to obtain geometric **QPTASs** [27].

Fig. 1: Relationships between parameters and an overview of our results (with theorem numbers, for weighted/unweighted variants). In the downwards direction (from tw to vc) parameter size increases and algorithmic results are inherited, while hardness results are inherited in the upwards direction.

2 Definitions and Preliminaries

We use standard graph-theoretic notation. For a graph G = (V, E), n = |V| denotes the number of vertices, m = |E| the number of edges, an edge $e \in E$ between $u, v \in V$ is denoted by (u, v), and for a subset $X \subseteq V$, G[X] denotes the graph induced by X. We use $\log(n)$ to denote the base-2 logarithm of n, while $\log_{1+\delta}(n)$ is the logarithm base- $(1 + \delta)$, for $\delta > 0$. Recall also that $\log_{1+\delta}(n) = \log(n)/\log(1+\delta)$. The functions $\lfloor x \rfloor$ and $\lceil x \rceil$, for $x \in \mathbb{R}$, denote the maximum integer that is not larger and the minimum integer that is not smaller than x, respectively. Further, we assume the reader has some familiarity with standard definitions from parameterized complexity theory, such as the classes FPT, W[1] (see [10,15,11]).

For a parameterized problem with parameter k, an FPT-AS is an algorithm which for any $\epsilon > 0$ runs in time $O^*(f(k, \frac{1}{\epsilon}))$ (i.e. FPT time when parameterized by $k + \frac{1}{\epsilon}$) and produces a solution at most a multiplicative factor $(1 + \epsilon)$ from the optimal (see [26]). We use $O^*(\cdot)$ to imply omission of factors polynomial in n. In this paper we present approximation schemes with running times of the form $(\log n/\epsilon)^{O(k)}$. These can be seen to imply an FPT running time by a well-known win-win argument: If a parameterized problem with parameter k admits, for some $\epsilon > 0$, an algorithm running in time $O^*((\log n/\epsilon)^{O(k)})$, then it also admits an algorithm running in time $O^*((k/\epsilon)^{O(k)})$.

Treewidth and pathwidth are standard notions in parameterized complexity that measure how close a graph is to being a tree or path ([3,4,23]). We will also use the parameters vertex cover number and feedback vertex set number of a graph G, which are the sizes of the minimum vertex set whose deletion leaves the graph edgeless, or acyclic, respectively. Finally, we will consider the related notion of tree-depth [29], which is defined as the minimum height of a rooted forest whose completion (the graph obtained by connecting each node to all its ancestors) contains the input graph as a subgraph. We will denote these parameters for a graph G as tw(G), pw(G), vc(G), fvs(G), and td(G), and will omit G if it is clear from the context. We recall the following well-known relations ([5,9]) between these parameters which justify the hierarchy given in Figure 1: For any graph G we have $tw(G) \leq pw(G) \leq td(G) \leq vc(G)$, $tw(G) \leq fvs(G) \leq vc(G)$.

We also recall here the two main complexity assumptions used in this paper [19,20]. The Exponential Time Hypothesis (ETH) states that 3-SAT cannot be solved in time $2^{o(n+m)}$ on instances with n variables and m clauses. The Strong Exponential Time Hypothesis (SETH) states that for all $\epsilon > 0$, there exists an integer q such that q-SAT (where q is the maximum size of any clause) cannot be solved in time $O((2 - \epsilon)^n)$.

3 Treewidth: SETH Lower Bound

In this section we show that for any fixed d > 2, the existence of any algorithm for the *d*-SCATTERED SET problem of running time $O^*((d-\epsilon)^{\text{tw}})$, for some $\epsilon > 0$, would imply the existence of some algorithm for *q*-SAT, of running

time $O^*((2-\delta)^n)$, for some $\delta > 0$ and any $q \ge 3$. First, let us briefly summarize the reduction for the SETH lower bound of $(2-\epsilon)^{tw}$ for INDEPENDENT SET from [25]. The reduction is based on the construction of n paths (one for each variable) on 2m vertices each, conceptually divided into m pairs of vertices (one for each clause), with each vertex signifying assignment of value 0 or 1 to the corresponding variable. A gadget is introduced for each clause, connected to the vertex of some path that signifies the assignment to the corresponding variable that would satisfy the clause. The pathwidth of the constructed graph (and thus also its treewidth) is (roughly) equal to the number of paths and thus a direct correspondence between a satisfying assignment and an independent set can be established, meaning an $O^*((2-\epsilon)^{tw})$ -time algorithm for INDEPENDENT SET would imply an $O^*((2-\epsilon)^n)$ -time algorithm for SAT, for any $\epsilon > 0$.

Intuitively, the reduction for INDEPENDENT SET needs to "embed" the 2^n possible variable assignments into the 2^{tw} states of some optimal dynamic program for the problem, while in our lower bound construction for *d*-SCATTERED SET we need to be able to encode these 2^n assignments by d^{tw} states and thus there can be no one-to-one correspondence between a variable and only one vertex in some bag of the tree decomposition (that the optimal dynamic program might assign states to); instead, every vertex included in some bag must carry information about the assignment for a *group* of variables. Furthermore, as now d > 2, in order to make the converse direction of our reduction to work, we need to make our paths sufficiently long to ensure that any solution will eventually settle into a pattern that encodes a consistent assignment, as the optimal *d*-scattered set may "cheat" by not selecting the same vertex from each part of some long path (periodically), a situation that would imply a different assignment for the appearances of the same variable for two different clauses (see also [8] and the SETH-based lower bound for DOMINATING SET from [25]).

Clause gadget \hat{C} : We first describe the construction of our clause gadget \hat{C} : this gadget has N input vertices and its purpose is to only allow for selection of one of these in any d-scattered set, along with another, standard selection. Given vertices v_1, \ldots, v_N , we first make N paths $A_i = (a_i^1, \ldots, a_i^{\lfloor d/2 \rfloor - 1}), \forall i \in [1, N]$ on $\lfloor d/2 \rfloor - 1$ vertices. We connect vertices a_i^1 to inputs v_i , while only for even d, we also make all vertices $a_i^{\lfloor d/2 \rfloor - 1}$ into a clique (all other endpoints of each path). We then make a path $B = (b^1, \ldots, b^{\lceil d/2 \rfloor + 1})$ and we connect its endpoint $b^{\lceil d/2 \rceil + 1}$ to all $a_i^{\lfloor d/2 \rfloor - 1}$. Figure 2 provides an illustration. Observe that any d-scattered set can only include one of the input vertices (as the distance between them is d-1) and the vertex b_1 , being the only option at distance d from all inputs.

Construction: We will describe the construction of a graph G, given some $\epsilon < 1, q \ge 3, d > 2$ and an instance ϕ of q-SAT with n variables, m clauses and at most q variables per clause. We first choose an integer $p = \lceil \frac{1}{(1-\lambda)\log_2(d)} \rceil$, for $\lambda = \log_d(d-\epsilon) < 1$ (i.e. p depends only on d and ϵ) and then group the variables of ϕ into $t = \lceil \frac{n}{\gamma} \rceil$ groups F_1, \ldots, F_t , for $\gamma = \lfloor \log_2(d)^p \rfloor$, being also the maximum size of any such group.

Fig. 2: A general picture of the clause gadget \hat{C} for even and odd d. Note the box indicating vertices forming a clique for the case of even d.

For each group F_{τ} of variables of ϕ , with $\tau \in [1, t]$, we make a simple gadget \hat{G}_{τ}^{1} that consists of p paths $P_{\tau}^{l} = (p_{1}^{l}, \ldots, p_{d}^{l})$ on d vertices each, for $l \in [1, p]$. We then make m(tp(d-1)+1) copies of this "column" of t gadgets $\hat{G}_{1}^{1}, \ldots, \hat{G}_{t}^{1}$ (i.e. t vertically arranged gadgets), that we connect horizontally (so that we have tp "long paths"): we connect each last vertex p_{d}^{l} from a gadget \hat{G}_{τ}^{j} to vertex p_{1}^{l} from the following gadget \hat{G}_{τ}^{j+1} , for all $l \in [1, p], \tau \in [1, t]$ and $j \in [1, m(tp(d-1))]$ (see Figure 3 (b) for an example).

Next, for every clause C_{μ} , with $\mu \in [1, m]$, we make tp(d-1) + 1 copies of the clause gadget \hat{C}^{j} , for $j \in [1, m(tp(d-1)+1)]$, where for each $\mu \in [1, m]$, the number of inputs in the tp(d-1)+1 copies is $N = q_{\mu}d^{p}/2$, where q_{μ} is the number of literals in clause C_{μ} . One clause is assigned to each column of gadgets, so that the first m columns correspond to one clause each, with tp(d-1)+1 repetitions of this pattern giving the complete association. Then, for every $\tau \in [1, t]$ we associate a set $S_{\tau} \subset \bigcup_{l \in [1,p]} P_{\tau}^{l}$, that contains exactly one vertex from each of the p paths in \hat{G}_{τ}^{j} , with an assignment to the variables in group F_{τ} . As there are at most $2^{\gamma} = 2^{\lfloor \log_2(d)^p \rfloor}$ assignments to the variables in F_{τ} and $d^p \geq 2^{\gamma}$ such sets S_{τ} , the association can be unique for each τ (i.e. for each row of gadgets). Now, for every literal appearing in clause C_{μ} , exactly half of the partial assignments to the group F_{τ} in which the literal's variable appears will satisfy it and thus, each of the $q_{\mu}d^p/2$ input vertices of the clause gadget will correspond to one literal and one assignment to the variables of the group that satisfy it.

Let v be an input vertex of a clause gadget C^j , corresponding to a literal of clause C_{μ} that is satisfied by a partial assignment to the variables of group F_{τ} that is associated with set $S_{\tau} \subset \bigcup_{l \in [1,p]} P_{\tau}^l$, containing exactly one vertex from each path $P_{\tau}^l, l \in [1,p]$, from gadget \hat{G}_{τ}^j . For even d, we then make a path $w_1, \ldots, w_{d/2-1}$ on d/2-1 vertices, connecting vertex w_1 to v and for each vertex $p_i^l \notin S$ of each path $P_{\tau}^l \in \hat{G}_{\tau}^j$ we also make a path $y_1, \ldots, y_{d/2-1}$ on d/2-1vertices, attaching endpoint y_1 to its corresponding path vertex p_i^l , while the other endpoints $y_{d/2-1}$ are all attached to vertex $w_{d/2-1}$ and to each other (into a clique). For odd d, we make a similar construction for each such v, only the number of vertices in constructed paths is now $\lfloor d/2 \rfloor$ instead of d/2 - 1 and vertices $y_{\lfloor d/2 \rfloor}$ are not made into a clique. Thus every input vertex v of some clause gadget is at distance exactly d-1 from every path vertex that does not belong to the set associated with its corresponding partial assignment (and thus exactly d from the only vertex per path that is), while the distances between any pair of other (i.e. intermediate) vertices via these paths are $\leq d-1$. This concludes our construction, while Figure 3 provides illustrations of the above.

In this way, a satisfying assignment for ϕ would correspond to a *d*-scattered set that selects the vertices in each gadget \hat{G}_{τ} that match the partial assignment S_{τ} for that group's variables F_{τ} in all m(tp(d-1)+1) columns, along with the corresponding input vertex from each clause gadget (implying the existence of a satisfied literal within the clause). On the other hand, for any *d*-scattered set of size (tp+2)m(tp(d-1)+1) in *G*, the maximum number of times it can "cheat" by not periodically selecting the "same" vertices in each column is tp(d-1). The number of columns being m(tp(d-1)+1), by the pigeonhole principle, there will always exist *m* consecutive columns for which the selection pattern does not change, from which a consistent assignment for all clauses can be extracted.

Fig. 3: (a): The connection of an input vertex v of a clause gadget \hat{C} to its corresponding path vertices in some \hat{G} , where vertices of set S_{τ} are circled and boxed vertices form a clique (for even d). (b): A simplified picture of the global construction, with some exemplative connecting paths between clause gadgets and path vertices shown as edges.

Theorem 1. For any fixed d > 2, if d-SCATTERED SET can be solved in $O^*((d - \epsilon)^{tw(G)})$ time for some $\epsilon > 0$, then there exists some $\delta > 0$, such that q-SAT can be solved in $O^*((2 - \delta)^n)$ time, for any $q \ge 3$.

4 Treewidth: Dynamic Programming Algorithm

8

In this section we present an $O^*(d^{tw})$ -time dynamic programming algorithm for the counting version of the *d*-SCATTERED SET problem. The input is a graph G = (V, E), a nice tree decomposition (\mathcal{X}, T) for G, where T = (I, F) is a tree and $\mathcal{X} = \{X_i | i \in I\}$ is the set of bags, while $\max_{i \in I} |X_i| - 1 = tw$, along with two numbers $k \in \mathbb{N}^+, d \geq 2$, while the output is the number of *d*-scattered sets of size *k* in *G*.

There is a table D_i associated with every node i of the tree decomposition with $X_i = \{v_0, \ldots, v_t\}$, while each table entry $D_i[\kappa, s_0, \ldots, s_t]$ contains the number of (distinct) d-scattered sets K of size $|K| = \kappa$ (its partial solution) and is indexed by a number $\kappa \in [1, k]$ and a t + 1-sized tuple (s_0, \ldots, s_t) of state-configurations, assigning a state $s_j \in [0, d-1]$ to each vertex v_j in the bag. There are d possible states for each vertex, designating its distance to the closest selection for the d-scattered set at the "current" stage of the algorithm (i.e. within the graph defined by each node of the tree decomposition), with vertices of zero state $s_j = 0$ being included in K, vertices of low state $s_j \in [1, \lfloor d/2 \rfloor]$ being at distance at least s_j from their closest selection and $d - s_j$ from the second closest, while vertices of high state $s_j \in \lfloor \lfloor d/2 \rfloor + 1, d - 1\rfloor$ are at distance at least s_j from K. That is, each partial solution is described by a given budget for selections (up to k) and the minimum distances of all vertices in the bag to an already selected vertex.

Based on this scheme, the inductive computations for each type of node of the nice tree decomposition are straightforward to obtain, yet a direct implementation would not lead to an algorithm of running time that matches the size of the constructed tables (d^{tw}) : using the above state-representation, the computations at a join node would require an additional 2^{tw} factor, as this is the number of possible combinations of previously computed partial solutions (from the tables of its children) that could be combined to give a partial solution for the new node. This can be avoided by an application of the *state changing* technique (or fast subset convolution, see [2,7,31] and Chapter 11 from [10]), for which it is also more convenient to *count* the number of solutions of each size $\kappa \in [1, k]$, instead of computing the maximum k for which a solution satisfying the given state-configuration exists.

Theorem 2. Given graph G, along with $d \in \mathbb{N}^+$ and nice tree decomposition (\mathcal{X}, T) of width tw for G, there exists an algorithm to solve the counting version of the d-SCATTERED SET problem in $O^*(d^{tw})$ time.

5 Vertex Cover, Feedback Vertex Set: W[1]-Hardness

In this section we show that the edge-weighted variant of the *d*-SCATTERED SET problem parameterized by vc + k is W[1]-hard via a reduction from k-MULTICOLORED INDEPENDENT SET, a well-known W[1]-complete problem (see [10]: given a graph G = (V, E), with V partitioned into k cliques $V = V_1 \uplus \cdots \uplus V_k$, $|V_i| = n, \forall i \in [1, k]$, we are asked to find a subset $S \subseteq V$, such that G[S] forms an independent set and $|S \cap V_i| = 1, \forall i \in [1, k]$.

Construction: Given an instance [G = (V, E), k] of k-MULTICOLORED INDE-PENDENT SET, we construct an instance [G' = (V', E'), k'] of edge-weighted d-SCATTERED SET where d = 6n. First, for every color class $V_i \subseteq V$ we create a set $P_i \subseteq V'$ of n vertices $p_l^i, \forall l \in [1, n], \forall i \in [1, k]$ (that directly correspond to the vertices of V_i). Next, for each $i \in [1, k]$ we make a pair of vertices a_i, b_i , connecting a_i to each vertex p_l^i by an edge of weight n+l, while b_i is connected to each vertex p_l^i by an edge of weight 2n-l. Next, for every non-edge $e \in \overline{E}$ (i.e. \overline{E} contains all pairs of vertices from V that are not connected by an edge from E) between two vertices from different V_{i_1}, V_{i_2} (with $i_1 \neq i_2$), we make a vertex u_e that we connect to vertices a_{i_1}, b_{i_1} and a_{i_2}, b_{i_2} . We set the weights of these edges as follows: suppose that e is a non-edge between the j_1 -th vertex of V_{i_1} and the j_2 -th vertex of V_{i_2} . We then set $w(u_e, a_{i_1}) = 5n - j_1, w(u_e, b_{i_1}) = 4n + j_1$ and $w(u_e, a_{i_2}) = 5n - j_2$, $w(u_e, b_{i_2}) = 4n + j_2$. Next, for every pair of i_1, i_2 we make two vertices $g_{i_1,i_2}, g'_{i_1,i_2}$. We connect g_{i_1,i_2} to all vertices u_e that correspond to non-edges e between vertices of the same pair V_{i_1}, V_{i_2} by edges of weight (6n-1)/2 and also g_{i_1,i_2} to g'_{i_1,i_2} by an edge of weight (6n+1)/2. In this way, a k-multicolored independent set in G corresponds to a 6n-scattered set in G' of size k^2 . This concludes the construction of G', with Figure 4 providing an illustration.

Fig. 4: A general picture of graph G', where the circled vertex is p_l^i and dotted lines match weights to edges.

Theorem 3. The edge-weighted d-SCATTERED SET problem is W[1]-hard parameterized by vc + k. Furthermore, if there is an algorithm for edge-weighted d-SCATTERED SET running in time $n^{o(\sqrt{vc}+\sqrt{k})}$ then the ETH is false.

Using essentially the same reduction (with minor modifications) we also obtain similar hardness results for unweighted *d*-SCATTERED SET parameterized by fvs: **Corollary 1.** The unweighted d-SCATTERED SET problem is W[1]-hard parameterized by fvs + k. Furthermore, if there is an algorithm for unweighted d-SCATTERED SET running in time $n^{o(fvs+\sqrt{k})}$ then the ETH is false.

6 Vertex Cover: FPT Algorithm

We next show that unweighted *d*-SCATTERED SET admits an FPT algorithm, in contrast to its weighted version (Theorem 3). Given graph *G* along with a vertex cover *C* of *G* and $d \ge 3$, our algorithm first defines an instance of PARTIAL SET PACKING, where elements may be *partially* included in some sets and then solves the problem by dynamic programming. In this variant, any element has a *coefficient* of inclusion in each set and a collection of sets is a solution if there is no pair of sets for which the sum of any element's coefficients is > 1.

We make a set for each vertex and an element for each vertex of C. Our aim is to identify two vertices (sets) as incompatible selections if there is some third "middle" vertex from C (elements), whose sum of distances to the other two is < d, based on the observation that for any vertex not belonging to the d-scattered set, only one selection can be at distance < d/2, yet any number of selections can be at distance $\ge d/2$ (consider a star as an example).

These coefficients of inclusion are then used to assign vertices of C to their closest possible selections, with complete inclusion (i.e. coefficient equal to 1) implying the distance is < d/2 and no inclusion (equal to 0) that it is > d/2. For the middle vertices, depending on the parity of d (and causing the difference in running times), we require either one (i.e. 1/2) or two (1/3 and 2/3) extra coefficients to be able to determine the exact position of a possible middle vertex from C (element) on the path between two potential selections (sets). If the sum of coefficients is ≤ 1 , the vertex from C is either a middle vertex on the path between the two selections or at distance < d/2 from only one of them. On the other hand, if the sum of coefficients is > 1, then the sum of distances from the vertex to the two selections is < d and the incompatibility of the sets implies the corresponding vertices cannot both belong in the d-scattered set.

Theorem 4. Given graph G, along with d > 2 and a vertex cover of size vc of G, there exists an algorithm solving the unweighted d-SCATTERED SET problem in $O^*(3^{vc})$ time for even d and $O^*(4^{vc})$ time for odd d.

7 Tree-depth: Tight ETH Lower Bound

In this section we consider the unweighted version of the *d*-SCATTERED SET problem parameterized by td. We first show the existence of an FPT algorithm of running time $O^*(2^{O(td^2)})$ and then a tight ETH-based lower bound. We begin with a simple upper bound argument, making use of the following fact on tree-depth, while the algorithm then follows from the dynamic programming procedure of Theorem 2 and the relationship between *d*, td and tw: **Lemma 1.** For any graph G = (V, E) we have $D(G) \leq 2^{td+1} - 2$, where D(G) denotes the graph's diameter.

Theorem 5. Unweighted d-SCATTERED SET can be solved in time $O^*(2^{O(td^2)})$.

Next we show a lower bound matching Theorem 5, based on the ETH, using a reduction from 3-SAT and a construction similar to the one used in Section 5.

Theorem 6. If unweighted d-SCATTERED SET can be solved in $2^{o(td^2)} \cdot n^{O(1)}$ time, then 3-SAT can be solved in $2^{o(n)}$ time.

8 Treewidth Revisited: FPT-AS

In this section we present an FPT approximation scheme (FPT-AS) for *d*-SCATTERED SET parameterized by tw. Given as input an edge-weighted graph $G = (V, E), k \in \mathbb{N}^+, d \geq 2$ and an arbitrarily small error parameter $\epsilon > 0$, our algorithm is able to return a set K, such that any $v, u \in K$ are at distance $d(v, u) \geq \frac{d}{1+\epsilon}$, in time $O^*((\operatorname{tw}/\epsilon)^{O(\operatorname{tw})})$, if G has a d-scattered set of size |K|.

Our algorithm makes use of a technique introduced in [24] (see also [1,21]) for approximating problems that are W-hard by treewidth. If the hardness of the problem arises from the need of the dynamic programming table to store tw large numbers (in our case, the distances of the vertices in the bag from the closest selection), we can significantly speed up the algorithm by replacing all values by the closest integer power of $(1 + \delta)$, for some appropriately chosen δ , thus reducing the table size from d^{tw} to $(\log_{(1+\delta)} d)^{\text{tw}}$. Of course, the calculations may result in values that are not integer powers of $(1 + \delta)$ that will thus have to be "rounded" to maintain the table size. This might introduce the accumulation of rounding errors, yet we are able to show that the error on any rounded value can be bounded by a function of the height of its corresponding bag and then make use of a theorem from [6] stating that any tree decomposition can be balanced so that its width remains almost unchanged and its total height becomes $O(\log n)$.

The rounding technique as applied in [24] employs randomization and an extensive analysis to procure the bounds on the propagation of error, while we only require a deterministic adaptation of the rounding process without making use of the advanced machinery there introduced, as for our particular case, the bound on the rounding error can be straightforwardly obtained. The main tool we require is the following definition of an addition-rounding operation, denoted by \oplus : for two non-negative numbers x_1, x_2 , we define $x_1 \oplus x_2 \coloneqq 0$, if $x_1 = x_2 = 0$. Otherwise, we set $x_1 \oplus x_2 \coloneqq (1 + \delta)^{\lfloor \log_{(1+\delta)}(x_1+x_2) \rfloor}$.

The integers we would like to approximately store are the states $s_j \in [1, d-1]$, representing the distance of a vertex v_j in bag X_i of the tree decomposition to the closest selection in the *d*-scattered set *K*, during computation of the dynamic programming algorithm. Let $\Sigma_{\delta} := \{0\} \cup \{(1 + \delta)^l | l \in \mathbb{N}\}$. Intuitively, Σ_{δ} is the set of rounded states that our modified algorithm may use. Of course, Σ_{δ} as defined is infinite, but we will only consider the set of values that are at most *d*, denoted by Σ_{δ}^d . In this way, the size of Σ_{δ}^d is reduced to $\log_{(1+\delta)}(d)$, that for $\delta = \frac{\epsilon}{O(\log n)}$, gives $|\Sigma_{\delta}^d| = O(\log(d)\log(n)/\epsilon)$ and we then rely on the well-known win-win parameterized argument given in Section 2 to get a running time of $O^*((\operatorname{tw}/\epsilon)^{O(\operatorname{tw})})$.

Modifications: First, we make use of an adaptation of the algorithm of Theorem 2 that works for the maximization version of the problem (albeit not optimally). We next explain the necessary modifications to the exact algorithm for use of the rounded states $\sigma \in \Sigma_{\delta}^d$. Consider a node *i* introducing vertex v_{t+1} : for a new entry to describe a proper extension to some previously computed partial solution, if the new vertex is of state $s_{t+1} \in [1, d-1]$ in the new entry, then there must be some vertex $v_j \in X_i$, such that $s_{t+1} \leq d(v_{t+1}, v_j) + s_j$ (the one for which this sum is minimized), i.e. we require that the new state of the introduced vertex matches its distance to some other vertex in the bag plus the state of that vertex (being the one "responsible" for connecting v_{t+1} to the partial solution). The rounded state σ_{t+1} for v_{t+1} must now satisfy: $\sigma_{t+1} \leq d(v_{t+1}, v_j) \oplus \sigma_j$, where \oplus is the operator defined above. Further, we define the symmetrical (around d/2) state $\bar{\sigma}$ for a given low state σ as the minimum state σ' for which $\sigma + \sigma' \geq \frac{d}{(1+\epsilon)}$ and we arbitrarily choose the computed states for the table of one of the children nodes to represent the new entries and $\bar{\sigma}$ to identify the symmetrical of each low state (from the other node's table).

Moreover, we require that the tree decompositions on which our algorithm is to be applied are rooted and of maximum depth $O(\log n)$. In [6] (Lemma 1), it is shown that any tree decomposition of width tw can be converted to a rooted and binary tree decomposition of depth $O(\log n)$ and width at most 3tw + 2 in $O(\log n)$ time and O(n) space. The following lemma employs the transformation to bound the error of any value calculated in this way, based on an appropriate choice of δ and therefore set Σ_{δ}^d of available values, by relating the rounded states σ computed at any node to the states s that the exact algorithm would use at the same node instead.

Lemma 2. Given ϵ and a tree decomposition (\mathcal{X}, T) with $T = (I, F), \mathcal{X} = \{X_i | i \in I\}$, where T is rooted, binary and of depth $O(\log n)$, there exists a constant C, such that for all rounded states $\sigma_j \in \Sigma_{\delta}^d$ it is $\sigma_j \geq \frac{s_j}{(1+\epsilon)}, \forall v_j \in X_i, \forall i \in I$, where $\delta = \frac{\epsilon}{C \log n}$.

Theorem 7. There is an algorithm which, given an edge-weighted instance of d-SCATTERED SET [G, k, d], a tree decomposition of G of width tw and a parameter $\epsilon > 0$, runs in time $O^*((tw/\epsilon)^{O(tw)})$ and finds a $d/(1 + \epsilon)$ -scattered set of size k, if a d-scattered set of the same size exists in G.

A Omitted Definitions

Lemma 3. If a parameterized problem with parameter k admits, for some $\epsilon > 0$, an algorithm running in time $O^*((\log n/\epsilon)^{O(k)})$, then it also admits an algorithm running in time $O^*((k/\epsilon)^{O(k)})$.

Proof. We consider two cases: if $k \leq \sqrt{\log n}$ then $(\log n/\epsilon)^{O(k)} = (1/\epsilon)^{O(k)} (\log n)^{O(\sqrt{\log n})} = O^*((1/\epsilon)^{O(k)})$. If on the other hand, $k > \sqrt{\log n}$ we have $\log n \leq k^2$, so $O^*((\log n/\epsilon)^{O(k)}) = O^*((k/\epsilon)^{O(k)})$.

A tree decomposition of a graph G = (V, E) is a pair (\mathcal{X}, T) with T = (I, F)a tree and $\mathcal{X} = \{X_i | i \in I\}$ a family of subsets of V (called *bags*), one for each node of T, with the following properties: 1) $\bigcup_{i \in I} X_i = V$; 2) for all edges $(v, w) \in E$, there exists an $i \in I$ with $v, w \in X_i$; 3) for all $i, j, k \in I$, if j is on the path from i to k in T, then $X_i \cap X_k \subseteq X_j$. The width of a tree decomposition $((I, F), \{X_i | i \in I\})$ is $\max_{i \in I} |X_i| - 1$. The *treewidth* of a graph G is the minimum width over all tree decompositions of G, denoted by tw(G).

Moreover, for rooted T, let $G_i = (V_i, E_i)$ denote the *terminal subgraph* defined by node $i \in I$, i.e. the induced subgraph of G on all vertices in bag i and its descendants in T. Also let $N_i(v)$ denote the neighborhood of vertex v in G_i and $d_i(u, v)$ denote the distance between vertices u and v in G_i , while d(u, v) (absence of subscript) is the distance in G.

In addition, a tree decomposition can be converted to a *nice* tree decomposition of the same width (in $O(\operatorname{tw}^2 \cdot n)$ time and with $O(\operatorname{tw} \cdot n)$ nodes): the tree here is rooted and binary, while nodes can be of four types: a) Leaf nodes *i* are leaves of *T* and have $|X_i| = 1$; b) Introduce nodes *i* have one child *j* with $X_i = X_j \cup \{v\}$ for some vertex $v \in V$ and are said to *introduce v*; c) Forget nodes *i* have one child *j* with $X_i = X_j \setminus \{v\}$ for some vertex $v \in V$ and are said to *forget v*; d) Join nodes *i* have two children denoted by i - 1 and i - 2, with $X_i = X_{i-1} = X_{i-2}$. Nice tree decompositions were introduced by Kloks in [23] and using them does not in general give any additional algorithmic possibilities, yet algorithm design becomes considerably easier.

Lemma 4. [5,9] For any graph G we have $tw(G) \le pw(G) \le td(G) \le vc(G)$, $tw(G) \le fvs(G) \le vc(G)$.

Additionally, we will require the equivalent definition of pathwidth via the mixed search number ms(G). In a mixed search game, a graph G is considered as a system of tunnels. Initially, all edges are contaminated by a gas and an edge is cleared by placing searchers at both its endpoints simultaneously or by sliding a searcher along the edge. A cleared edge is re-contaminated if there is a path from a contaminated edge to the cleared edge without any searchers on its vertices or edges. A search is a sequence of operations that can be of the following types: (a) placement of a new searcher on a vertex; (b) removal of a searcher from a vertex; (c) sliding a searcher on a vertex along an incident edge and placing the searcher on the other end. A search strategy is winning if after its termination all edges are cleared. The mixed search number of G, denoted by ms(G), is the minimum number of searchers required for a winning strategy of mixed searching on G.

Lemma 5. [30] For a graph G, it is $pw(G) \le ms(G) \le pw(G) + 1$.

The SET PACKING problem is defined as follows: given an integer k, a universe $\mathcal{U} = \{u_1, \ldots, u_n\}$ of elements and a family $\mathcal{S} = \{S_1, \ldots, S_m\}$ of subsets of \mathcal{U} , is there a subfamily $S \subseteq \mathcal{S}$ of subsets (a packing), such that all sets in S are pairwise disjoint, and the size of the packing is $|S| \ge k$?

Finally, k-MULTICOLORED INDEPENDENT SET is a well-known W[1]-complete problem (see [10]) and is defined as follows: we are given a graph G = (V, E), with V partitioned into k cliques $V = V_1 \uplus \cdots \uplus V_k$, $|V_i| = n, \forall i \in [1, k]$, and are asked to find a subset $S \subseteq V$, such that G[S] forms an independent set and $|S \cap V_i| = 1, \forall i \in [1, k].$

B Omitted proofs

From Section 3, Treewidth: SETH Lower Bound

Clause gadget \hat{C} : We first describe the construction of our clause gadget \hat{C} : this gadget has N input vertices and its purpose is to only allow for selection of one of these in any d-scattered set, along with another, standard selection. Given vertices v_1, \ldots, v_N , we first make N paths $A_i = (a_i^1, \ldots, a_i^{\lfloor d/2 \rfloor - 1}), \forall i \in [1, N]$ on $\lfloor d/2 \rfloor - 1$ vertices. We connect vertices a_i^1 to inputs v_i , while only for even d, we also make all vertices $a_i^{\lfloor d/2 \rfloor - 1}$ into a clique (all other endpoints of each path). We then make a path $B = (b^1, \ldots, b^{\lceil d/2 \rfloor + 1})$ and we connect its endpoint $b^{\lceil d/2 \rfloor + 1}$ to all $a_i^{\lfloor d/2 \rfloor - 1}$. This concludes the construction of clause gadget \hat{C} , while Figure 5 provides an illustration. Observe that any d-scattered set can only include one of the input vertices (as the distance between them is d - 1) and the vertex b_1 , being the only option at distance d from all inputs.

Fig. 5: A general picture of the clause gadget \hat{C} for even and odd d. Note the box indicating vertices forming a clique for the case of even d.

Construction: We will describe the construction of a graph G, given some $\epsilon < 1$ and an instance ϕ of q-SAT with n variables, m clauses and at most q variables per clause. We first choose an integer $p \geq \frac{1}{(1-\lambda)\log_2(d)}$, for $\lambda = \log_d(d-\epsilon) < 1$, for reasons that become apparent in the proof of Theorem 1. Note that for the results of this section, d, q and p are considered constants. We then group the variables of ϕ into $t = \lceil \frac{n}{\gamma} \rceil$ groups F_1, \ldots, F_t , for $\gamma = \lfloor \log_2(d)^p \rfloor$, being also the maximum size of any such group.

Next, for each group F_{τ} of variables of ϕ , with $\tau \in [1, t]$, we make a simple gadget \hat{G}_{τ}^{1} that consists of p paths $P_{\tau}^{l} = (p_{1}^{l}, \ldots, p_{d}^{l})$ on d vertices each, for $l \in [1, p]$. We then make m(tp(d-1) + 1) copies of this "column" of t gadgets $\hat{G}_{1}^{1}, \ldots, \hat{G}_{t}^{1}$, that we connect horizontally (so that we have tp "long paths"): we connect each last vertex p_{d}^{l} from a gadget \hat{G}_{τ}^{j} to vertex p_{1}^{l} from the following gadget \hat{G}_{τ}^{j+1} , for all $l \in [1, p], \tau \in [1, t]$ and $j \in [1, m(tp(d-1))]$.

Next, for every clause C_{μ} , with $\mu \in [1, m]$, we make tp(d-1) + 1 copies of the clause gadget \hat{C}^{j} , for $j \in [1, m(tp(d-1)+1)]$, where for each $\mu \in [1, m]$, the number of inputs in the tp(d-1)+1 copies is $N = q_{\mu}d^{p}/2$, where q_{μ} is the number of literals in clause C_{μ} . One clause is assigned to each column of gadgets, so that the first m columns correspond to one clause each, with tp(d-1)+1 repetitions of this pattern giving the complete association. Then, for every $\tau \in [1, t]$ we associate a set $S_{\tau} \subset \bigcup_{l \in [1,p]} P_{\tau}^{l}$, that contains exactly one vertex from each of the p paths in \hat{G}_{τ}^{j} , with an assignment to the variables in group F_{τ} . As there are at most $2^{\gamma} = 2^{\lfloor \log_2(d)^p \rfloor}$ assignments to the variables in F_{τ} and $d^p \geq 2^{\gamma}$ such sets S_{τ} , the association can be unique for each τ . Now, for every literal appearing in clause C_{μ} , exactly half of the partial assignments to the group F_{τ} that contains the literal's variable will satisfy it and thus, each of the $q_{\mu}d^{p}/2$ input vertices of the clause gadget will correspond to one literal and one assignment to the variables of the group that satisfy it.

Let v be an input vertex of a clause gadget \hat{C}^{j} , corresponding to a literal of clause C_{μ} that is satisfied by a partial assignment to the variables of group F_{τ} that is associated with set $S_{\tau} \subset \bigcup_{l \in [1,p]} P_{\tau}^l$, containing exactly one vertex from each path $P_{\tau}^{l}, l \in [1, p]$, from gadget \hat{G}_{τ}^{j} . For even d, we then make a path $w_1, \ldots, w_{d/2-1}$ on d/2-1 vertices, connecting vertex w_1 to v and for each vertex $p_i^l \notin S$ of each path $P_{\tau}^l \in \hat{G}_{\tau}^j$ we also make a path $y_1, \ldots, y_{d/2-1}$ on d/2 - 1vertices, attaching endpoint y_1 to its corresponding path vertex p_i^l , while the other endpoints $y_{d/2-1}$ are all attached to vertex $w_{d/2-1}$ and to each other (into a clique). For odd d, we make a similar construction for each such v, only the number of vertices in constructed paths is now |d/2| instead of d/2 - 1 and vertices $y_{\lfloor d/2 \rfloor}$ are not made into a clique. In this way, every input vertex v of some clause gadget is at distance exactly d-1 from every path vertex that does not belong to the set associated with its corresponding partial assignment (and thus exactly d from the only vertex per path that is), while the distances between any intermediate vertices via these paths are $\leq d-1$. This concludes our construction, while Figure 6 provides illustrations of the above.

Fig. 6: (a): The connection of an input vertex v of some clause gadget \hat{C} to its corresponding path vertices in some \hat{G} , where vertices of set S_{τ} are circled and boxed vertices form a clique (for even d). (b): A simplified picture of the global construction, with some exemplative connecting paths between clause gadgets and path vertices shown as edges.

Lemma 6. If ϕ has a satisfying assignment, then G has a d-scattered set of size (tp+2)m(tp(d-1)+1).

Proof. Given a satisfying assignment for ϕ , we will show the existence of a d-scattered set K of G of size |K| = (tp+2)m(tp(d-1)+1). Set K will include one vertex from each of the p paths in each gadget \hat{G}_{τ}^{j} , with $\tau \in [1,t], j \in [1,m(tp(d-1)+1)]$ and two vertices from each clause gadget \hat{C}^{j} . In particular, for each group F_{τ} of variables we consider the restriction of the assignment for ϕ to these variables and identify the set S_{τ} associated with this partial assignment, adding all vertices of S_{τ} from each \hat{G}_{τ}^{j} into set K. Then, for each clause C_{μ} , we identify one satisfied literal (which must exist as the assignment for ϕ is satisfying) and the vertex v that corresponds to that literal and the partial assignment associated with set S_{τ} selected from the group of paths $P_{\tau}^{l}, l \in [1, p]$ within gadget \hat{G}_{τ}^{j} , for group F_{τ} , in which that literal's variable appears in. We add to K every such vertex v and also vertex b_{1} from each clause gadget \hat{C}^{j} , for all $j \in [1, m(tp(d-1)+1)]$, thus completing the selection and what remains is to show that K is indeed a d-scattered set of G.

To that end, observe that the pattern of our $p \cdot m(tp(d-1)+1)$ selections of all vertices from every set S_{τ} for each $\tau \in [1, t]$ is repeating: we have selected every *d*-th vertex from each "long path", since the association between sets S_{τ} and partial assignments for F_{τ} is the same of each τ . Thus on each of the *tp* long paths, every selected vertex is at distance exactly *d* both from its predecessor and its follower. Furthermore, for each clause gadget \hat{C}^{j} , with $j \in [1, m(tp(d-1)+1)]$, selected vertices v and b_1 are at distance exactly d via the gadget, while vertex v is at distance exactly d from each selected $p_i^l \in S_{\tau}$ from each path P_{τ}^l , $l \in [1, p]$, as there are only paths of length d-1 from v to the neighbors p_{i-1}^l, p_{i+1}^l of the selected vertex from each path. Finally, observe that the distance between vertices on different paths P_{τ}^l (and thus possible selections) via the paths attached to some input vertex is always $\geq 2d-2$.

Lemma 7. If G has a d-scattered set of size (tp+2)m(tp(d-1)+1), then ϕ has a satisfying assignment.

Proof. Given a d-scattered set K of G of size |K| = (tp+2)m(tp(d-1)+1), we will show the existence of a satisfying assignment for ϕ . First, observe that from each gadget \hat{G}^j_{τ} , for $\tau \in [1, t], j \in [1, m(tp(d-1)+1)]$, at most p vertices can be selected, one from each path $P_{\tau}^{l}, l \in [1, p]$ within each gadget. This leaves 2 vertices to be selected from each column $i \in [1, m(tp(d-1)+1)]$ of gadgets. As the distances between some input vertex v and some path vertex p_i^l is equal to d only if the path vertex belongs to the set S_{τ} associated with the partial assignment to the variables of F_{τ} that would satisfy the literal (whose variable belongs to F_{τ}) corresponding to the input vertex v and d-1 otherwise, while the distances between any pair of input vertices are d-1 via the gadget with only vertex b_1 at distance exactly d from each input vertex, it is not hard to see that the only option is to select each vertex b_1 and one input vertex from each gadget C^{j} , for $j \in [1, m(tp(d-1)+1)]$: no path vertex p_{i}^{l} could be selected with any vertex on the paths attached to some input vertex v, while no other vertex but b_1 could be selected with some input vertex of each clause gadget. Furthermore, the selection of an input vertex v must also be in agreement with each selection from the p paths to which v is connected to (via the paths of length d-1), i.e. the selected vertices from each path must be exactly the set S_{τ} that is associated with the partial assignment that satisfies the literal corresponding with v.

Next, we require that there exists at least one $o \in [0, tp(d-1)]$ for every $\tau \in [1, t]$ for which $K \cap \{\bigcup_{l \in [1, p]} P_{\tau}^l\}$ is the same in all gadgets $\hat{G}_{\tau}^{mo+\pi}$ with $\pi \in [1, m]$, i.e. that there exist m successive copies of the gadget for which the pattern of selection of vertices from paths P_{τ}^l does not change. As noted above, set K must contain one vertex from each such path in each gadget, while the distance between any two successive selections (on the same "long path") must be at least d. Now, depending on the starting selection, observe that the pattern can "shift towards the right" at most d-1 times, without affecting whether the total number of selections is exactly m(tp(d-1)+1) from each "long path": the first vertex of a path can be selected within a gadget, the second vertex can be selected from its follower, the third from the one following it and so on. For each $l \in [1, p]$, this can happen at most d-1 times, thus at most p(d-1) for each $\tau \in [1, t]$ and tp(d-1) over all τ . By the pigeonhole principle, there must thus exist an $o \in [0, tp(d-1)]$ such that no such shift happens among the gadgets $\hat{G}_{\tau}^{mo+\pi}$, for all $\tau \in [1, t]$ and $\pi \in [1, m]$.

Our assignment for ϕ is then given by the selections for K in each gadget \hat{G}_{τ}^{mo+1} for this o: for every group F_{τ} we consider the selection of vertices from

 P_{τ}^{l} for $l \in [1, p]$, forming subset S_{τ} and its associated partial assignment to the variables of F_{τ} . In this way we get an assignment to all the variables of ϕ . To see why this also satisfies every clause C_{π} with $\pi \in [1, m]$, consider clause gadget $\hat{C}^{mo+\pi}$: there must be an input vertex v selected from this gadget, corresponding to a satisfying partial assignment for some literal of C_{π} , that must be at distance exactly d from each path selection that together give subset S_{τ} , the subset associated with this satisfying partial assignment.

Lemma 8. Graph G has treewidth $tw(G) \leq tp + qd^p/2 + d$.

Proof. We will in fact show a pathwidth bound of $pw(G) \le tp + qd^p/2 + d$ by providing a mixed strategy to clean G using $tp + qd^p/2 + d$ searchers. The claimed bound on the treewidth then follows from lemmas 4 and 5.

We initially place one searcher on every first vertex p_1^l of every path P_{τ}^l in each gadget \hat{G}_{τ}^1 for all $l \in [1, p]$ and $\tau \in [1, t]$. We also place a searcher on vertex b_1 of clause gadget \hat{C}^1 , also one on each of its $q_{\mu}d^p/2$ vertices $a_i^{\lfloor d/2 \rfloor - 1}$ (between the inputs and b_1) and finally one searcher on each of the d - 1 vertices $y_{d/2-1}$ (or $y_{\lfloor d/2 \rfloor}$ for odd d) that are connected through a $w_1, \ldots, w_{d/2-1}$ path to each input vertex (or $w_1, \ldots, w_{\lfloor d/2 \rfloor}$).

We then slide the searcher on b_1 over the path $b_1, \ldots, b^{\lceil d/2 \rceil}$ until all the path's edges as well as the edges between $b^{\lceil d/2 \rceil}$ and every $a_i^{\lfloor d/2 \rfloor -1}$ are cleaned (the clique edges between the $a_i^{\lfloor d/2 \rfloor -1}$ for even d are also clean). We then slide the searchers from the $a_i^{\lfloor d/2 \rfloor -1}$ along each path to each input vertex and from there on along the paths $w_1, \ldots, w_{d/2-1}$ (or $w_{\lfloor d/2 \rfloor}$ for odd d). In this way all these paths and the edges between the $w_{d/2-1}$ and $y_{d/2-1}$ (or $w_{\lfloor d/2 \rfloor}$ and $y_{\lfloor d/2 \rfloor}$ for odd d) are cleaned and we can slide the searchers from each $y_{d/2-1}$ down to each y_1 (being adjacent to one path vertex each). We then slide all tp searchers from the first vertices p_1^l along their paths P_{τ}^l for $l \in [1, p]$ in each gadget \hat{G}_{τ}^1 . After all edges of the first column have been cleaned in this way, we slide the tp searchers from the vertices of each path of the following column, we remove the searchers from the vertices of the clause gadget (and adjacent paths) and place them on their corresponding starting positions on the following column. We then repeat the above process until all columns have been cleaned. We thus use at most $tp + qd^p/2 + d$ searchers simultaneously, where $qd^p/2 + d = O(1)$.

Theorem 1. For any fixed d > 2, if d-SCATTERED SET can be solved in $O^*((d - \epsilon)^{tw(G)})$ time for some $\epsilon > 0$, then there exists some $\delta > 0$, such that q-SAT can be solved in $O^*((2 - \delta)^n)$ time, for any $q \ge 3$.

Proof. Assuming the existence of some algorithm of running time $O^*((d - \epsilon)^{\operatorname{tw}(G)}) = O^*(d^{\lambda\operatorname{tw}(G)})$ for *d*-SCATTERED SET, where $\lambda = \log_d(d - \epsilon)$, we construct an instance of *d*-SCATTERED SET given a formula ϕ of *q*-SAT, using the above construction and then solve the problem using the $O^*((d - \epsilon)^{\operatorname{tw}(G)})$ -time algorithm. Correctness is given by Lemma 6 and Lemma 7, while Lemma 8 gives the upper bound on the running time:

$$O^*(d^{\lambda \operatorname{tw}(G)}) \le O^*\left(d^{\lambda(tp+f(d,\epsilon,q))}\right) \tag{1}$$

$$\leq O^* \begin{pmatrix} \lambda_p \left\lceil \frac{n}{\lfloor \log_2(d)^p \rfloor} \right\rceil \end{pmatrix}$$
(2)

$$\leq O^* \begin{pmatrix} \lambda_p \frac{n}{\lfloor \log_2(d)^p \rfloor} + \lambda_p \\ d \end{pmatrix}$$
(3)

$$\leq O^* \begin{pmatrix} \lambda \frac{np}{\lfloor p \log_2(d) \rfloor} \end{pmatrix} \tag{4}$$

$$\leq O^* \left(\frac{\delta' \frac{n}{\log_2(d)}}{d} \right) \tag{5}$$

$$\leq O^*(2^{\delta''n}) = O((2-\delta)^n)$$
 (6)

for some $\delta, \delta', \delta'' < 1$. Observe that in line (2) the function $f(d, \epsilon, q) = qd^p/2 + d$ is considered constant, as is λp in line (4), while in line (5) we used the fact that there always exists a $\delta' < 1$ such that $\lambda \frac{p}{\lfloor p \log_2(d) \rfloor} = \frac{\delta'}{\log_2(d)}$, as we have:

$$\begin{split} p \log_2(d) - 1 < \lfloor p \log_2(d) \rfloor \\ \Leftrightarrow \frac{\lambda p \log_2(d)}{p \log_2(d) - 1} > \frac{\lambda p \log_2(d)}{\lfloor p \log_2(d) \rfloor}, \\ \text{from which, by substitution, we get } \frac{\lambda p \log_2(d)}{p \log_2(d) - 1} > \delta', \\ \text{now requiring } \frac{\lambda p \log_2(d)}{p \log_2(d) - 1} \le 1, \\ \text{or } p \ge \frac{1}{(1 - \lambda) \log_2(d)}, \end{split}$$

that is precisely our definition of p. This concludes the proof.

From Section 4, Treewidth: Dynamic Programming Algorithm

Table description: There is a table D_i associated with every node $i \in I$ of the tree decomposition with $X_i = \{v_0, \ldots, v_t\}, 0 \leq t \leq tw$, while each table entry $D_i[\kappa, s_0, \ldots, s_t]$ contains the number of (disjoint) *d*-scattered sets $K \subseteq V_i$ of size $|K| = \kappa$ (its partial solution) and is indexed by a number $\kappa \in [1, k]$ and a t + 1-sized tuple (s_0, \ldots, s_t) of state-configurations, assigning a state $s_j \in [0, d-1]$ to each vertex $v_j, \forall j \in [0, t]$. There are *d* possible states for each vertex, designating its distance to the closest selection at the "current" stage of the algorithm:

- Zero state $s_j = 0$ signifies vertex v_j is considered for selection in the *d*-scattered set and is at distance at least *d* from any other such selection: $\forall u \in K : d(u, v_j) \geq d.$
- Low states $s_j \in [1, \lfloor d/2 \rfloor]$ signify vertex v_j is at distance at least s_j from its closest selection and at least $d - s_j$ from the second closest: $\forall u, w \in K | d(u, v_j) \leq d(w, v_j) : d(u, v_j) \geq s_j \wedge d(w, v_j) \geq d - s_j$.
- High states $s_j \in [\lfloor d/2 \rfloor + 1, d-1]$ signify vertex v_j is at distance at least s_j from its closest selection: $\forall u \in K : d(u, v_j) \geq s_j$.

For a node $i \in I$, each table entry $D_i[\kappa, s_0, \ldots, s_t]$ contains the number of *d*-scattered sets $K \subseteq V_i$ of the terminal subgraph G_i , such that the situation of each vertex in the corresponding bag is being described by the particular state configuration (s_0, \ldots, s_t) indexing this entry. The computation of each entry is based on the type of node the table is associated with (leaf, introduce, forget, or join), previously computed entries of the table associated with the preceding node(s) and the structure of the node's terminal subgraph. In particular, we have $\forall i \in I, D_i[\kappa, s_0, \ldots, s_t] : [1, k] \times [0, d-1]^{t+1} \mapsto \mathbb{N}^0$, where $0 \le t \le$ tw. The inductive computation of all table entries for each type of node follows.

Leaf node i with $X_i = \{v_0\}$:

$$D_i[\kappa, s_0] \coloneqq \begin{cases} 1 & , \text{ if } s_0 = 0, \kappa = 1; \\ 1 & , \text{ if } s_0 > 0, \kappa = 0; \\ 0 & , \text{ otherwise.} \end{cases}$$

Leaf nodes contain only one vertex and there is one *d*-scattered set that includes this vertex for $(s_0 = 0, \kappa = 1)$ and one *d*-scattered set that does not (for $s_0 > 0$, $\kappa = 0$).

Introduce node i with $X_i = X_{i-1} \cup \{v_{t+1}\}$:

$$D_{i}[\kappa, s_{0}, \dots, s_{t}, s_{t+1}] \coloneqq \begin{cases} D_{i-1}[\kappa, s_{0}, \dots, s_{t}], & \text{if } s_{t+1} \in [1, d-1] \text{ and} \\ s_{t+1} \leq \min_{v_{j} \in X_{i-1}} (d(v_{t+1}, v_{j}) + s_{j}); \\ D_{i-1}[\kappa', s'_{0}, \dots, s'_{t}], & \text{if } s_{t+1} = 0, \kappa' = \kappa - 1 \text{ and } \forall v_{j} \in X_{i-1} \text{ with } s_{j} = 0, \\ & \text{it is } d(v_{t+1}, v_{j}) \geq d, \text{ and} \\ & \forall v_{j} \in X_{i-1} \text{ with } d(v_{t+1}, v_{j}) \leq \lfloor d/2 \rfloor, \\ & \text{it is } s_{j} \leq d(v_{t+1}, v_{j}) \text{ and } s'_{j} = d - s_{j}, \\ & \text{with } s'_{j} = s_{j}, \text{ if } d(v_{t+1}, v_{j}) > \lfloor d/2 \rfloor; \\ 0, & \text{otherwise.} \end{cases}$$

When a vertex is introduced, for previously computed partial solutions to be correctly extended, we require that its given state matches the distance/state conditions of the other vertices in the bag, while if the introduced vertex is considered for selection, then the previous entries we examine must ensure this selection is possible.

22

Forget node i with $X_i = X_{i-1} \setminus \{v_{t+1}\}$:

$$D_i[\kappa, s_0, \dots, s_t] \coloneqq \sum_{s_{t+1} \in [0, d-1]} \{ D_{i-1}[\kappa, s_0, \dots, s_t, s_{t+1}] \}.$$

The correct value for each entry is the sum over all states of the forgotten vertex v_i , where the size of the *d*-scattered sets is κ .

Join node i with $X_i = X_{i-1} = X_{i-2}$: Given state-tuple (s_0, \ldots, s_t) , we assume (without loss of generality) that for some $t' \in [0, t]$ (if any) it is $s_j \in [1, \lfloor d/2 \rfloor], \forall j \in [0, t']$ and also $\min_{\forall v_l \in X_i | s_l = 0} d(v_j, v_l) > \lfloor d/2 \rfloor$, while all other vertices are $v_{t'+1}, \ldots, v_t$. Now, let $\mathcal{S}_{t'}^{\leq}$ denote the set of all possible tuples $S = (s_0^{\leq}, \ldots, s_{t'}^{\leq})$, where each state s_j^{\leq} is either the same state s_j , or its symmetrical (around d/2):

$$\mathcal{S}_{t'}^{\leq} \coloneqq \{ (s_0^{\leq}, \dots, s_{t'}^{\leq}) | \forall j \in [0, t'] : \{ (s_j^{\leq} = s_j) \lor (s_j^{\leq} = d - s_j) \} \},$$

while for some tuple $S \in \mathcal{S}_{t'}^{\leq}$, let \bar{S} denote the complementary tuple (where the state of each vertex is likewise reversed) and also let κ'' denote the number of zero states in $(s_{t'+1}, \ldots, s_t)$. Then we have:

$$D_{i}[\kappa, s_{0}, \dots, s_{t}] \coloneqq \sum_{S \in \mathcal{S}_{t'}^{\leq}} \{ D_{i-1}[\kappa', S, s_{t'+1}, \dots, s_{t}] \cdot D_{i-2}[\kappa - \kappa' + \kappa'', \bar{S}, s_{t'+1}, \dots, s_{t}] \}.$$

For join nodes, the bags of both children contain the same set of vertices, yet the partial solutions characterized by the entries of each table concern distinct terminal subgraphs G_{i-1} and G_{i-2} . For state-configurations where some vertices are of low state (that is not justified by the presence of some vertex of zero state within the bag), the closest selection to these vertices (that gives the state) might be in any of the two terminal subgraphs, but not both: if the "target" state is $s_j \in [1, \lfloor d/2 \rfloor]$, then there might be a selection in G_{i-1} at distance s_j but there must not be another selection in G_{i-2} at distance $\leq d - s_j$ (and vice-versa).

State changes: The computations at a join node as described above would add an additional factor in the complexity of our algorithm if implemented directly, yet this can be avoided by an application of the state changing technique (or fast subset convolution, see [2,7,31] and Chapter 11 from [10]): since the number of entries involved can be exponential in tw (due to the size of $\mathcal{S}_{t'}^{\leq}$), in order to efficiently compute the table for a join node *i*, we will first transform the tables D_{i-1}, D_{i-2} of its children into tables D_{i-1}^*, D_{i-2}^* of a new type that employs a different state representation, for which the join operation can be efficiently performed to produce table D_i^* , that we will finally transform back to table D_i , thus progressing with our dynamic programming algorithm.

In particular, each entry $D_i^*[\kappa, s_1, \ldots, s_t]$ of the new table will be an aggregate of entries $D_i[\kappa, s_0, \ldots, s_t]$ of the original table, with its value equal to the sum of the appropriate values of the corresponding entries. For vertex v_j , each low state $s_j \in [1, \lfloor d/2 \rfloor]$ in the new state signification for table D_i^* that is not justified by the presence of an appropriate selection within the bag (i.e. its minimum distance to any zero-state vertex is at least $\lfloor d/2 \rfloor + 1$) will correspond to both the same low state s_j and its symmetrical high state $d - s_j$ from the original signification. Observe that these correspondences exactly parallel the definition of set $S_{t'}^{\leq}$ used in the original computations.

First, let D_i^* be a copy of table D_i . The transformation then works in t steps, vertex-wise: we require that all entries $D_i^*[\kappa, s_0^*, \ldots, s_t^*]$ contain the sum of all entries of D_i where for low states s_j^* (that are also not justified by some present selection), it is $s_j^* = s_j$ or $s_j^* = d - s_j$, and all other vertex-states and κ are fixed: at step j, we add $D_i^*[\kappa, s_0, \ldots, s_j, \ldots, s_t] = D_i[\kappa, s_0, \ldots, s_j, \ldots, s_t] + D_i[\kappa, s_0, \ldots, d - s_j, \ldots, s_t]$ if $s_j \in [1, \lfloor d/2 \rfloor]$ and $\min_{\forall v_l \in X_i \mid s_i = 0} d(v_j, v_l) > \lfloor d/2 \rfloor$. We then proceed to the next step for v_{j+1} until table D_i^* is computed. Observe that the above procedure is fully reversible:¹ to invert table D_i^* back to table D_i , we again work in t steps, vertex-wise: we first let D_i be a copy of D_i^* and then at step j for all other vertex-states and κ fixed, we subtract $D_i[\kappa, s_0, \ldots, s_j, \ldots, s_t] = D_i^*[\kappa, s_0, \ldots, s_j, \ldots, s_t] - D_i^*[\kappa, s_0, \ldots, d - s_j, \ldots, s_t]$ if $s_j \in [1, \lfloor d/2 \rfloor]$ and $\min_{\forall v_l \in X_i \mid s_i = 0} d(v_j, v_l) > \lfloor d/2 \rfloor$. For both transformations, we perform at most one addition per $k \cdot d^{t+1}/2$ entries for each step $j \in [0, t]$.

Thus we can compute table D_i^* by simply multiplying the values of the two corresponding entries from D_{i-1}^*, D_{i-2}^* , as they now contain all required information for this state representation, with the inverse transformation of the result giving table D_i :

$$D_i^*[\kappa, s_0, \dots, s_t] \coloneqq \sum_{\kappa'=0}^{\kappa'=\kappa} D_{i-1}^*[\kappa', s_0, \dots, s_t] \cdot D_{i-2}^*[\kappa - \kappa' + \kappa'', s_0, \dots, s_t].$$

Theorem 2. Given graph G, along with $d \in \mathbb{N}^+$ and nice tree decomposition (\mathcal{X}, T) of width tw for G, there exists an algorithm to solve the counting version of the d-SCATTERED SET problem in $O^*(d^{tw})$ time.

Proof. Let $U_i(\kappa, s_0, \ldots, s_t) = \{K \subseteq V_i | K \cap X_i = \{v_j \in X_i | s_j = 0\}, |K| = \kappa, \forall u, v \in K : d(u, v) \geq d\}$ be the set of all *d*-scattered sets in G_i of size κ . To show correctness of our algorithm we need to establish that for every node $i \in I$, each table entry $D_i[\kappa, s_0, \ldots, s_t]$ contains the size of a partial solution to the problem as restricted to G_i , i.e. the size of this set $|U_i(\kappa, s_0, \ldots, s_t)|$, such that the distance between every pair of vertices in K is at least d, while for every vertex $v_j \in X_i$, its state for this entry describes its situation within this partial solution. In particular, we need to show the following:

¹ This is the reason for *counting* the number of solutions for each κ : there is no additive inverse operation for the max-sum semiring, yet the sum-product ring is indeed equipped with subtraction.

$$\forall i \in I, \forall \kappa \in [1, k], \forall (s_0, \dots, s_t) \in [0, d-1]^{t+1}, 0 \le t < tw:$$
(7)

$$D_i[\kappa, s_0, \dots, s_t] = |U_i(\kappa, s_0, \dots, s_t)|:$$
(8)

$$\{\forall u, w \in K : d(u, w) \ge d\} \land \tag{9}$$

$$\wedge \{\forall v_j \in X_i | s_j \in [1, \lfloor d/2 \rfloor], \forall u, w \in K | d(u, v_j) \le d(w, v_j) :$$

$$(10)$$

$$(u, v_j) \ge s_j \wedge d(w, v_j) \ge d - s_j \} \wedge \tag{11}$$

$$\land \{ \forall v_j \in X_i | s_j \in [\lfloor d/2 \rfloor + 1, d-1], \forall u \in K : d(u, v_j) \ge s_j \}.$$
(12)

In words, the above states that for every node $i, \kappa \in [1, k]$ and all possible state-configurations (s_0, \ldots, s_t) (7), table entry $D_i[\kappa, s_0, \ldots, s_t]$ contains the size of set $U_i(\kappa, s_0, \ldots, s_t)$ containing all subsets K of V_i (that include all vertices $v_j \in X_i$ of state $s_j = 0$) of size $|K| = \kappa$ (8), such that the distance between every pair of vertices $u, w \in K$ is at least d (9), for every vertex $v_j \in X_i$ with low state $s_j \in [1, \lfloor d/2 \rfloor]$ and a pair of vertices u, w from K with u closer to v_j than w (10), its distance to u is at least equal to its state s_j , while its distance to w is at least $d - s_j$ (11), while for every vertex $v_j \in X_i$ with high state $s_j \in [\lfloor d/2 \rfloor + 1, d - 1]$ and a vertex u from K, its state s_j is at most its distance to u (12). This is shown by induction on the nodes $i \in I$:

d

- Leaf node *i* with $X_i = \{v_0\}$: This is the base case of our induction. There is only one *d*-scattered set *K* in V_i of size $\kappa = 1$, for which (9-12) is true, that includes v_0 and only one for $\kappa = 0$ that does not. In the following cases, we assume (our inductive hypothesis) that all entries of D_{i-1} (and D_{i-2} for join nodes) contain the correct number of sets *K*.
- Introduce node *i* with $X_i = X_{i-1} \cup \{v_{t+1}\}$: For entries with $s_j \in [1, \lfloor d/2 \rfloor]$, validity of (9,12) is not affected, while for (10-11): it is $s_{t+1} \leq d(v_{t+1}, v_j) + s_j$ for some vertex $v_j \in X_{i-1}$, for which, by the induction hypothesis we have that $s_j \leq d(u, v_j)$ and $d - s_j \leq d(w, v_j)$, where *u* is the closest selection to v_j and *w* the second closest. To see the same holds for v_{t+1} , observe that $s_{t+1} \leq d(v_{t+1}, v_j) + d(u, v_j) \leq d(v_{t+1}, u)$ (by substitution) and $d - s_j \leq d(w, v_j) \Rightarrow d - d(w, v_j) \leq s_j \Rightarrow d - d(w, v_j) + d(v_j, v_{t+1}) \leq d(v_{t+1}, v_j) + s_j \Rightarrow$ $d - d(w, v_{t+1}) \leq s_{t+1} \Rightarrow d - s_{t+1} \leq d(w, v_{t+1}).$

For entries with $s_{t+1} \in [\lfloor d/2 \rfloor + 1, d-1]$, validity of (9-11) is not affected, while for (12): it is $s_{t+1} \leq d(v_{t+1}, v_j) + s_j$ for some vertex $v_j \in X_{i-1}$, for which, by the induction hypothesis we have that $s_j \leq d(u, v_j)$ and thus $s_{t+1} \leq d(v_{t+1}, v_j) + d(u, v_j) \leq d(v_{t+1}, u)$.

For entries with $s_{t+1} = 0$, observe that the low states s_j of vertices $v_j \in X_{i-1}$ in the new entry with $d(v_{t+1}, v_j) \leq \lfloor d/2 \rfloor$ (for otherwise their situation has not changed by addition of v_{t+1} with $s_{t+1} = 0$) would correspond to a high original state $s'_j = d - s_j$ in the previously computed entry, for which partial solution we know that $d(v_j, u) \geq s'_j, \forall u \in K$, or that the previously closest selection was at distance at least s'_j (10-11). For high states s_j of vertices $v_j \in X_{i-1}$, the requirement is exactly $d(v_{t+1}, v_j) \geq s_j$ (12) and finally, for (9), if there was some $u \in K$ such that $u \notin X_{i-1}$ and $d(u, v_{t+1}) < d$, then there must be some $v_j \in X_{i-1}$ (on the path between u and v_{t+1}), for which if $d(v_{t+1}, v_j) \leq \lfloor d/2 \rfloor$ and s_j is low then (12) was false (as s'_j must have been high and matching $d(u, v_j)$), while if $d(v_{t+1}, v_j) > \lfloor d/2 \rfloor$ and s_j is high, then (10-11) was false (in all other cases it would not be $d(u, v_{t+1}) < d$).

- Forget node *i* with $X_i = X_{i-1} \setminus \{v_{t+1}\}$: In a forget node, the only difference for the partial solutions in which the forgotten vertex was of state $s_{t+1} = 0$ is that now vertex v_{t+1} is included in set *K* only and not X_i . Thus, due to (9), the correct number is indeed the sum over all states for v_{t+1} .
- Join node i with $X_i = X_{i-1} = X_{i-2}$: Observe that for (9), if there was a pair $u, w \in K \cap X_i$ or $u \in K \cap X_i, w \in K \setminus X_i$ at d(u, w) < d, then (9) was not true for either i-1 or i-2, while if there was a pair $u \in K \cap V_{i-1} \setminus X_{i-1}, w \in K \cap V_{i-2} \setminus X_{i-2}$ with d(u, w) < d, then there must be some vertex $v_j \in X_i$ (on the path between the two) for which (11) was not true. For (10-12), observe that for vertices v_j of low state s_j , (10-11) must have been true for either i-1 or i-2 and (12) for the other, while for vertices v_j of high state s_j it suffices that (12) must have been true for both.

For the algorithm's complexity, there are $k \cdot d^{\text{tw}}$ entries for each table D_i of any node $i \in I$, with $|I| = O(\text{tw} \cdot |V|)$ for nice tree decomposition $(\mathcal{X}, T = (I, F))$, while any entry can be computed in time O(1) for leaf and introduce nodes, O(d)for forget nodes, while the state changes can be computed in $O(k \cdot \text{tw} \cdot d^{\text{tw}})$ time, with each entry of the transformed table D_i^* computed in O(k) time. \Box

From Section 5, Vertex Cover, Feedback Vertex Set: W[1]-Hardness

Construction: First, for every set $V_i \subseteq V$ we create a set $P_i \subseteq V'$ of n vertices $p_l^i, \forall l \in [1, n], \forall i \in [1, k]$ (that directly correspond to the vertices of V_i). Next, for each $i \in [1, k]$ we make a pair of vertices a_i, b_i , connecting a_i to each vertex p_l^i by an edge of weight n + l, while b_i is connected to each vertex p_l^i by an edge of weight 2n - l. Next, for every non-edge $e \in \overline{E}$ (i.e. \overline{E} contains all pairs of vertices from V that are not connected by an edge from E) between two vertices from different V_{i_1}, V_{i_2} (with $i_1 \neq i_2$), we make a vertex u_e that we connect to vertices a_{i_1}, b_{i_1} and a_{i_2}, b_{i_2} . We set the weights of these edges as follows: suppose that e is a non-edge between the j_1 -th vertex of V_{i_1} and the j_2 -th vertex of V_{i_2} . We then set $w(u_e, a_{i_1}) = 5n - j_1, w(u_e, b_{i_1}) = 4n + j_1$ and $w(u_e, a_{i_2}) = 5n - j_2$, $w(u_e, b_{i_2}) = 4n + j_2$. Next, for every pair of i_1, i_2 we make two vertices g_{i_1,i_2} , g'_{i_1,i_2} . We connect g_{i_1,i_2} to all vertices u_e that correspond to non-edges e between vertices of the same pair V_{i_1}, V_{i_2} by edges of weight (6n - 1)/2 and also g_{i_1,i_2} , with Figure 7 providing an illustration.

Lemma 9. If G has a k-multicolored independent set, then G' has a 6n-scattered set of size $k + 2\binom{k}{2} = k + k(k-1) = k^2$.

Proof. Let $I \subseteq V$ be a multicolored independent set in G of size k and $v_{l_i}^i$ denote the vertex selected from each V_i , or $I := \{v_{l_1}^1, \ldots, v_{l_k}^k\}$. Let $S \subseteq V'$ include the set of vertices $p_{l_i}^i$ in G' that correspond to each $v_{l_i}^i$. For any pair $i, j \in [1, k]$ of indices

26

Fig. 7: A general picture of graph G', where the circled vertex is p_l^i and dotted lines match weights to edges.

with $i \neq j$, let u_e be the vertex corresponding to the non-edge between vertices $v_{l_i}^i, v_{l_j}^j \in I$. All these u_e vertices exist, as I is a k-multicolored independent set. We include all these u_e vertices in S and also every $g'_{i,j}$ that is connected to $g_{i,j}$ that each such u_e is connected to. Now S is of size $k + 2\binom{k}{2}$ and we claim it is a 6n-scattered set: all selected vertices $p_{l_i}^i$ are at distance $n + l_i + 5n - l_i = 6n$ via a_i and distance $2n - l_i + 4n + l_i = 6n$ via b_i from any selected vertex u_e that corresponds to a non-edge "adjacent" to their corresponding $v_{l_i}^i$, while every selected vertex u_e corresponding to a non-edge between two vertices of groups V_{i_1}, V_{i_2} is at distance (6n - 1)/2 + (6n + 1)/2 = 6n from every selected vertex g'_{i_1,i_2} that is connected to g_{i_1,i_2} that connects all such u_e vertices between these groups.

Lemma 10. If G' has a 6n-scattered set of size $k + 2\binom{k}{2} = k + k(k-1) = k^2$, then G has a k-multicolored independent set.

Proof. Let $S \subseteq V'$ be the 6*n*-scattered set, with $|S| = k + 2\binom{k}{2}$. As the distance via $g_{i,j}$ between any two vertices u_e, u_h corresponding to non-edges between vertices of the same groups V_i, V_j is 6n - 1, set S can contain at most one such vertex for every such pair of groups, their number being $\binom{k}{2}$. Since the size of S is $k + 2\binom{k}{2}$, the set must also contain one other vertex per group, the only choices available being vertices $g'_{i,j}$ at distance (6n - 1)/2 + (6n + 1)/2 = 6n from any such u_e , leaving the k choices for at most one vertex from each P_i , as the distance between any pair $p_{l_1}^i, p_{l_2}^i$ is $2n + l_1 + l_2 < 6n$ via a_i and $4n - l_1 - l_2 < 6n$ via b_i . Now, let $u_e \in S$ be a selected vertex corresponding to a non-edge between vertices $v_{l_i}^i, v_{l_j}^j$ from groups V_i, V_j and $p_{o_i}^i, p_{o_j}^j \in S$ be the vertices selected from P_i, P_j . Vertex u_e

is at distance $5n - l_i + n + o_i = 6n + o_i - l_i$ via a_i and $4n + l_i + 2n - o_i = 6n + l_i - o_i$ via b_i from $p_{o_i}^i \in P_i$, while at distance $5n - l_j + n + o_j = 6n + o_j - l_j$ via a_j and $4n + l_j + 2n - o_j = 6n + l_j - o_j$ via b_j from $p_{o_j}^j \in P_j$. It is not hard to see that if $o_i \neq l_i$ then u_e and $p_{l_i}^i$ cannot be together in S, while also if $o_j \neq l_j$ then u_e and $p_{l_j}^j$ cannot be together in S. Thus, there must be no edge between every pair of vertices $v_{l_i}^i, v_{l_j}^j$ that correspond to $p_{l_i}^i, p_{l_j}^j \in S$, meaning the set I that includes all such $v_{l_i}^i$ is a k-multicolored independent set.

Theorem 3. The edge-weighted d-SCATTERED SET problem is W[1]-hard parameterized by vc + k. Furthermore, if there is an algorithm for edge-weighted d-SCATTERED SET running in time $n^{o(\sqrt{vc}+\sqrt{k})}$ then the ETH is false.

Proof. Observe that the set $Q \subset V'$ that includes all vertices $a_i, b_i, \forall i \in [1, k]$ and all vertices $g_{i,j}, \forall i \neq j \in [1, k]$ is a vertex cover of G', as all edges have exactly one endpoint in Q. This means $vc(G') \leq 2k + \binom{k}{2} = O(k^2)$. In addition, the relationship between the sizes of the solutions of d-SCATTERED SET and k-MULTICOLORED INDEPENDENT SET is $k' = |S| = k + 2\binom{k}{2} = O(k^2)$. Thus, the construction along with lemmas 9 and 10, indeed imply the statement. \Box

Corollary 1. The unweighted d-SCATTERED SET problem is W[1]-hard parameterized by fvs+k. Furthermore, if there is an algorithm for unweighted d-SCATTERED SET running in time $n^{o(fvs+\sqrt{k})}$ then the ETH is false.

Proof. The modifications to the above construction that we require are the following: each edge e of weight w(e) is substituted by a path of length w(e), apart from the edge between every g_{i_1,i_2} to every g'_{i_1,i_2} that is now a path of length d-1 = 6n-1 and all edges between every g_{i_1,i_2} to all adjacent u_e that correspond to non-edges between vertices of pair V_{i_1}, V_{i_2} that are now only a single edge. In this way, Lemma 9 goes through unchanged, while for Lemma 10, it suffices to observe that no two vertices anywhere on the paths between some g_{i_1,i_2} and some a_i, b_i could be selected instead of the intended selection of g'_{i_1,i_2} and some u_e that matches the selections from V_{i_1}, V_{i_2} , as the distance between any two vertices are not exactly some a_i, b_i is always < 2d = 12n, while if the selected vertices are not exactly some g'_{i_1,i_2} and (the correct) u_e , then the minimum distance between these selections and the closest selection from V_{i_1}, V_{i_2} will be less than d.

It is not hard to see that the set Q containing all $a_i, b_i, \forall i \in [1, k]$ is a feedback vertex set of G', as removal of all these vertices results in an acyclic graph, hence $fvs(G') \leq O(k)$.

From Section 6, Vertex Cover: FPT Algorithm

Theorem 4. Given graph G, along with d > 2 and a vertex cover of size vc of G, there exists an algorithm solving the unweighted d-SCATTERED SET problem in $O^*(3^{vc})$ time for even d and $O^*(4^{vc})$ time for odd d. *Proof.* Let C be the given vertex cover of G and $I = V \setminus C$ be the remaining independent set. Let also $Y \subseteq I$ be the subset of vertices from I with a unique neighborhood in C, i.e. for two vertices $u, v \in I$ with N(u) = N(v), set Y only contains one of them. Observe that the size of Y is thus exponentially bounded by the size of $C: |Y| \leq 2^{|C|}$.

For an instance of our PARTIAL SET PACKING variant, let $\mathcal{U} = \{u_1, \ldots, u_n\}$ be the universe of elements and $\mathcal{S} = \{S_1, \ldots, S_m\}$ be the set family. Further, for even d, we introduce a weight function $w(u_i, S_j) : \mathcal{U} \times \mathcal{S} \mapsto \{0, 1/2, 1\}$, giving the *coefficient* of element u_i for inclusion in set S_j , where 0 implies the element is not included in the set, 1/2 implies *partial* and 1 *complete* inclusion. For odd d, the weight function $w(u_i, S_j) : \mathcal{U} \times \mathcal{S} \mapsto \{0, 1/3, 2/3, 1\}$ allows more values for partial inclusion. In our solutions to this variant we will allow any number of sets to partially include any element, yet if any set in the solution completely includes some element, then no other set that includes the same element either partially, or completely, can also be part of the same solution, i.e. a collection of subsets $S \subseteq \mathcal{S}$ will be a solution, if for every element $u_i \in \mathcal{U}$, the sum for any two pairs is at most 1: $\max_{S_a, S_b \in S} \{w(u_i, S_a) + w(u_i, S_b)\} \leq 1$.

We then define our PARTIAL SET PACKING instance as follows: we make an element $u_i \in \mathcal{U}$ for every vertex of C and a set $S_j \in \mathcal{S}$ for every vertex of $C \cup Y$. We thus have |C| elements and $|C| + |Y| \leq |C| + 2^{|C|}$ sets. For even d, an element u_i with corresponding vertex $v \in C$ is included in some set S_j with corresponding vertex $v \in C$ is included in some set S_j with corresponding vertex $v \in C$ is included in some set S_j with corresponding vertex z partially (or $w(u_i, S_j) = 1/2$), if d(v, z) = d/2. For odd d, an element u_i with corresponding vertex $v \in C$ is included in some set S_j with corresponding vertex z partially (or $w(u_i, S_j) = 1/2$), if d(v, z) = d/2. For odd d, an element u_i with corresponding vertex $v \in C$ is included in some set S_j with corresponding vertex z completely (or $w(u_i, S_j) = 1$) if $d(v, z) < \lfloor d/2 \rfloor$, 2/3-partially ($w(u_i, S_j) = 2/3$) if $d(v, z) = \lfloor d/2 \rfloor$ and 1/3-partially ($w(u_i, S_j) = 1/3$) if $d(v, z) = \lfloor d/2 \rfloor$.

In the classic dynamic programming procedure for SET PACKING we store a table OPT[U, j] that contains, for every subset of elements $U \subseteq \mathcal{U}$ and $j \in [1, m]$ the maximum number of subsets that can be selected from $\{S_1, \ldots, S_j\}$, such that no element of U is included in any of them. The dynamic programming procedure then first computes for j = 1: $OPT[U, 1] \coloneqq 1$, if $U \cap S_j = \emptyset$ and 0 otherwise, while for $j = 2, \ldots, m$ it is: $OPT[U, j+1] \coloneqq \max\{OPT[U, j], OPT[U \cup S_{j+1}, j] + 1\}$ if $S_{j+1} \cap U = \emptyset$ and only $OPT[U, j+1] \coloneqq OPT[U, j]$ otherwise.

We will create a similar table OPT[U, j] for every $j \in [1, m]$ and every $U = \{(u_i \in \mathcal{U}, w(u_i, U))\}$ (of the possible $3^{|\mathcal{U}|}$ or $4^{|\mathcal{U}|}$), storing the maximum number of sets that can be selected from $\{S_1, \ldots, S_j\}$ to form a partial solution $S' \subseteq \{S_1, \ldots, S_j\}$, so that for any element u_i it is $\max_{S_l \in S'} \{w(u_i, S_l) + w(u_i, U)\} \leq 1$. Letting the union operator $A \cup B$ transfer maximum inclusion, i.e. $w(u_i, A \cup B) = \max\{w(u_i, A), w(u_i, B)\}$, and substituting the check for $U \cap S_j = \emptyset$ by $\forall u_i \in U \cup S_j : w(u_i, U) + w(u_i, S_j) \leq 1$ in the above procedure, we can solve the PARTIAL SET PACKING instance in $O(mn4^n)$ time (and only $O(mn3^n)$ for even d).

Given a solution $S \subseteq S$ to our PARTIAL SET PACKING instance, we will show that it corresponds to a solution for the original instance of *d*-SCATTERED SET. First observe that on any shortest path v_0, \ldots, v_d between vertices v_0, v_d , we know that any vertex v_i will either be included in C, or both its neighbors v_{i-1}, v_{i+1} on the path will be included instead, as otherwise both edges adjacent to v_i are not covered by C.

Consider first the case where d is even. On the shortest path between two vertices v_0, v_d that are at distance d from each other there will be one (*middle*) vertex $v_{d/2}$ at distance d/2 from both and if $v_{d/2} \in C$ then the corresponding element will be partially included in both sets corresponding to v_0, v_d , while if $v_{d/2} \notin C$, each of the elements corresponding to its neighbors $v_{d/2-1}, v_{d/2+1}$ on the path will be completely included in one set each and thus both sets can be used in solution S. For two vertices v_0, v_{d-1} at distance d-1 from each other, there will be one vertex $v_{d/2}$ at distance d/2 from v_0 and d/2 - 1 from v_{d-1} and also one vertex $v_{d/2-1}$ at distance d/2 - 1 from v_0 and d/2 from v_{d-1} . If $v_{d/2} \in C$, then its corresponding element is included partially by 1/2 in the set corresponding to vertex v_0 and completely by 1 in the set corresponding to vertex v_{d-1} . Otherwise, if $v_{d/2-1} \in C$, then its corresponding element is included completely by 1 in the set corresponding to vertex v_0 and partially by 1/2 in the set corresponding to vertex v_{d-1} . Thus in both cases these two sets cannot be included together in S. The argument also holds if the distance between the two vertices is smaller than d-1.

Next, if d is odd, on the shortest path between two vertices v_0, v_d that are at distance d from each other there will be two middle vertices $v_{\lfloor d/2 \rfloor}, v_{\lfloor d/2 \rfloor}$ at distances $\lfloor d/2 \rfloor$ and $\lceil d/2 \rceil$ from each. Now, vertex $v_{\lfloor d/2 \rfloor}$ will be at distance $\lfloor d/2 \rfloor$ from v_0 and distance $\lfloor d/2 \rfloor$ from v_d and if $v_{\lfloor d/2 \rfloor} \in C$ its element will be included by 2/3 in the set corresponding to v_0 and by 1/3 in the set corresponding to v_d . Similarly, if $v_{\lceil d/2 \rceil} \in C$, its element will be included by 1/3 in the set corresponding to v_0 and by 2/3 in the set corresponding to v_d . Thus in both cases the two sets can be included together in S. For two vertices v_0, v_{d-1} at distance d-1 from each other, if vertex $v_{\lfloor d/2 \rfloor} \in C$, then its element will be included by 2/3 in both sets corresponding to v_0, v_{d-1} , while if $v_{\lfloor d/2 \rfloor} \notin C$, then we have that both its neighbors $v_{\lfloor d/2 \rfloor - 1}, v_{\lfloor d/2 \rfloor + 1} \in C$. Now, the element corresponding to $v_{\lfloor d/2 \rfloor - 1}$ will be completely included by 1 in the set corresponding to v_0 and partially by 1/3 in the set corresponding to v_{d-1} , while the element corresponding to $v_{\lfloor d/2 \rfloor+1}$ will likewise be included partially by 1/3 in the set corresponding to v_0 and completely by 1 in the set corresponding to v_{d-1} . Thus in both cases, these two sets cannot be included together in S, while the argument also holds if the distance between the vertices is smaller than d-1.

As the number of sets in our PARTIAL SET PACKING instance is $m = |C| + |Y| \le |V|$ and the number of elements is n = |C| = vc, the total running time of our algorithm is bounded by $O^*(4^{\text{vc}})$ for odd d and $O^*(3^{\text{vc}})$ for even d.

From Section 7, Tree-depth: Tight ETH Lower Bound

Lemma 1. For any graph G = (V, E) we have $D(G) \leq 2^{td+1} - 2$, where D(G) denotes the graph's diameter.

Proof. We use the following equivalent inductive definition of tree-depth: $td(K_1) = 0$ while for any other graph G = (V, E) we set $td(G) = 1 + \min_{u \in V} td(G \setminus u)$ if G is connected, and $td(G) = \max_C td(G[C])$ if G is disconnected, where the maximum ranges over all connected components of G.

We prove the claim by induction. The inequality is true for K_1 , whose diameter is 0. For the inductive step, the interesting case is when G = (V, E) is connected, since otherwise we can assume that the claim has been shown for each connected component and we are done. Let $u \in V$ be such that $td(G) = 1 + td(G \setminus u)$. Consider two vertices $v_1, v_2 \in V \setminus \{u\}$ which are at maximum distance in G. If v_1, v_2 are in the same connected component of $G' := G \setminus u$, then $d_G(v_1, v_2) \leq d_{G'}(v_1, v_2) \leq D(G') \leq 2^{td(G')+1} - 2 \leq 2^{td(G)+1} - 2$, where we have used the inductive hypothesis on G'. So, suppose that v_1, v_2 are in different connected components of G'. It must be the case that u has a neighbor in the component of v_1 (call it v'_1) and in the component of v_2 (call it v'_2), because G is connected. We have $d_G(v_1, v_2) \leq d_G(v_1, v'_1) + 2 + d_G(v_2, v'_2) \leq d_{G'}(v_1, v'_1) + 2 + d_{G'}(v_2, v'_2) \leq 2D(G') + 2 \leq 2 \cdot 2^{td(G')+1} - 2 = 2^{td(G)+1} - 2$.

Theorem 5. Unweighted d-SCATTERED SET can be solved in time $O^*(2^{O(td^2)})$.

Proof. The main observation is that we can assume that $d \leq D(G)$, because otherwise the problem is trivial. Hence, by Lemma 1 we have $d \leq 2^{\text{td}+1}$. We can now rely on Lemma 4 to get tw \leq td, and the algorithm of Theorem 2 which runs in time $O^*(d^{\text{tw}})$ gives the desired running time.

Construction: Given an instance ϕ of 3-SAT on n variables and m clauses, where we can assume that m = O(n) (by the Sparsification Lemma, see [20]), we will create an instance [G = (V, E)] of the unweighted d-SCATTERED SET problem where $d = 6 \cdot c^{\sqrt{n}}$ for an appropriate constant c (to simplify notation, we assume without loss of generality that \sqrt{n} is an integer). We first group the clauses of ϕ into \sqrt{n} equal-sized groups $F_1, \ldots, F_{\sqrt{n}}$ and as a result, each group involves $O(\sqrt{n})$ variables, with $2^{O(\sqrt{n})}$ possible assignments to the variables of each group. We select c appropriately so that each group F_i has at most $c^{\sqrt{n}}$ possible partial assignments ϕ_i^i for the variables of clauses in F_i .

We then create for each $i \in \{1, \ldots, \sqrt{n}\}$, a set P_i of at most $c^{\sqrt{n}}$ vertices $p_1^i, \ldots, p_{c^{\sqrt{n}}}$, such that each vertex of P_i represents a partial assignment to the variables of F_i that satisfies all clauses of F_i . We then create for each $i \in \{1, \ldots, \sqrt{n}\}$ a pair of vertices a_i, b_i and we connect a_i to each vertex p_l^i by a path of length $c^{\sqrt{n}} + l$, while b_i is connected to each vertex p_l^i by a path of length $2 \cdot c^{\sqrt{n}} - l$. Now each P_i contains all a_i, b_i and $p_l^i, i \in \{1, \ldots, c^{\sqrt{n}}\}$.

Finally, for every two *non-conflicting* partial assignments ϕ_l^i, ϕ_o^j , with $l, o \in [1, c^{\sqrt{n}}]$ and $i, j \in [1, \sqrt{n}]$, i.e. two partial assignments that do not assign conflicting values to any variable, we create a vertex $u_{l,o}^{i,j}$ that we connect to vertices a_i, b_i and a_j, b_j : if $p_l^i \in P_i$ is the vertex corresponding to ϕ_l^i and $p_o^j \in P_j$ is the vertex corresponding to ϕ_o^j , then vertex $u_{l,o}^{i,j}$ is connected to a_i by a path of length $5 \cdot c^{\sqrt{n}} - l$ and to b_i by a path of length $4 \cdot c^{\sqrt{n}} + l$, as well as to a_j by a path of length $5 \cdot c^{\sqrt{n}} - o$ and to b_j by a path of length $4 \cdot c^{\sqrt{n}} + o$. Next, for every pair i, j we make two vertices $g_{i,j}, g'_{i,j}$. We connect $g_{i,j}$ to all vertices $u_{l,o}^{i,j}$ (for any l, o) by a single edge and also $g_{i,j}$ to $g'_{i,j}$ by a path of length $6 \cdot c^{\sqrt{n}} - 1$. This concludes our construction and Figure 8 provides an illustration.

Fig. 8: A general picture of graph G, where straight lines imply paths of length equal to the number indicated by dotted lines, while the circled vertex is p_i^i .

Lemma 11. If ϕ has a satisfying assignment, then there exists a $6 \cdot c^{\sqrt{n}}$ -scattered set in G of size $\sqrt{n} + 2\binom{\sqrt{n}}{2} = n$.

Proof. Consider the satisfying assignment for ϕ and let $\phi_{l_i}^i$, with $l_i \in [1, c^{\sqrt{n}}]$ and $i \in [1, \sqrt{n}]$, be the restriction of that assignment for all variables appearing in clauses of group F_i . We claim the set K, consisting of all vertices $p_{l_i}^i$ corresponding to $\phi_{l_i}^i$, all vertices $g'_{i,j}$ and all $u_{l,o}^{i,j}$ vertices for which we have selected p_l^i and p_o^j (all these vertices exist, as the corresponding partial assignments are non-conflicting), is a *d*-scattered set for G of size $|K| = \sqrt{n} + 2\binom{\sqrt{n}}{2} = n$: all selected vertices $p_{l_i}^i$ are at distance $c^{\sqrt{n}} + l_i + 5 \cdot c^{\sqrt{n}} - l_i = 6 \cdot c^{\sqrt{n}}$ via a_i and distance $2 \cdot c^{\sqrt{n}} - l_i + 4 \cdot c^{\sqrt{n}} + l_i = 6 \cdot c^{\sqrt{n}}$ via b_i from any selected vertex $u_{l_i,l_j}^{i,j}$, while every selected $u_{l_i,l_j}^{i,j}$ is at distance $6 \cdot c^{\sqrt{n}} - 1 + 1 = 6 \cdot c^{\sqrt{n}}$ from every selected $g'_{i,j}$.

Lemma 12. If there exists a $6 \cdot c^{\sqrt{n}}$ -scattered set in G of size $\sqrt{n} + 2\binom{\sqrt{n}}{2} = n$, then ϕ has a satisfying assignment.

Proof. Let $S \subseteq V$ be the $6 \cdot c^{\sqrt{n}}$ -scattered set in G, with |S| = n. For every pair $i, j \in [1, \sqrt{n}]$, set S cannot contain more than one vertex from the paths between $g_{i,j}$ and a_i, b_i, a_j, b_j , as the distance between any pair of such vertices is always $< 2 \cdot 6 \cdot c^{\sqrt{n}}$ (due to the single edges between $g_{i,j}$ and any $u_{l_i,l_j}^{i,j}$). Likewise, set S cannot contain more than two vertices from the paths between $g'_{i,j}$ and a_i, b_i, a_j, b_j , as the maximum sum of distances between any three such vertices is $< 3 \cdot 6 \cdot c^{\sqrt{n}}$. Since $|S| = \sqrt{n} + 2(\frac{\sqrt{n}}{2})$, set S must also contain \sqrt{n} other vertices and due to the distance between any pair of vertices p_i^i, p_o^i from the same group P_i being $< 4 \cdot \sqrt{n}$, there must be one selection from each group P_i . Furthermore, for two such selections $p_{l_i}^i, p_{l_j}^j$, the only option for the other two selections (for this pair of groups i, j) is to select vertices $g'_{i,j}$ and $u_{l_i,l_j}^{i,j}$, since the distances from $p_{l_i}^i, p_{l_j}^j$ to $u_{l_i,l_j}^{i,j}$ (through a_i, b_i, a_j, b_j) will only be equal to $6 \cdot c^{\sqrt{n}}$ if these selections (and indices) match, with the only remaining option at distance $6 \cdot c^{\sqrt{n}}$ (for any choice of $u_{l_i,l_j}^{i,j}$) being vertex $g'_{i,j}$.

Lemma 13. The tree-depth of G is $2\sqrt{n} + \lceil \log(6 \cdot c^{\sqrt{n}}) \rceil + 1 = O(\sqrt{n})$.

Proof. We again employ the alternative definition of tree-depth used in Lemma 1. Consider graph G after removal of all vertices $a_i, b_i, \forall i \in [1, \sqrt{n}]$. The graph now consists of $\sqrt{n} \cdot c^{\sqrt{n}}$ paths of length $< 3 \cdot c^{\sqrt{n}}$ through each vertex in P_i and $\binom{\sqrt{n}}{2}$ trees, considered rooted at each vertex $g_{i,j}$. The maximum distance in each such tree between a leaf and its root is $6 \cdot c^{\sqrt{n}} - 1$ (for vertex $g'_{i,j}$) and the claim then follows, as paths of length n have tree-depth exactly $\lceil \log(n+1) \rceil$ (this can be shown by repeatedly removing the middle vertex of each path). By the definition of tree-depth, after removal of $2\sqrt{n}$ vertices from G, the maximum tree-depth of each resulting disconnected component is $\lceil \log(6 \cdot c^{\sqrt{n}}) \rceil = \lceil \sqrt{n} \cdot \log(c) + \log(6) \rceil$.

Theorem 6. If unweighted d-SCATTERED SET can be solved in $2^{o(td^2)} \cdot n^{O(1)}$ time, then 3-SAT can be solved in $2^{o(n)}$ time.

Proof. Suppose there is an algorithm for *d*-SCATTERED SET with running time $2^{o(\mathrm{td}^2)}$. Given an instance ϕ of 3-SAT, we use the above construction to create an instance [G = (V, E)] of *d*-SCATTERED SETwith $d = 6 \cdot c^{\sqrt{n}}$, in time $O(\sqrt{n} \cdot c^{\sqrt{n}} + c^{2\sqrt{n}})$. As, by Lemma 13, we have $\mathrm{td}(G) \leq O(\sqrt{n})$, using the supposed algorithm for *d*-SCATTERED SET we can decide whether ϕ has a satisfying assignment in time $2^{o(\mathrm{td}^2)} \cdot n^{O(1)} = 2^{o(n)}$.

From Section 8, Treewidth revisited: FPT-AS

Modifications: Our approximation algorithm will be a modification of the exact dynamic programming for *d*-SCATTERED SET, given in Section 4. For the approximation algorithm, we will make use of an adaptation of this algorithm of Theorem 2, that works for the maximization version of the problem instead of the counting version (albeit not optimally). We first describe the necessary

modifications to the counting version and then the subsequent changes for use of our rounded values.

The algorithm for the maximization version needs the following changes: for a leaf node i we set $D_i[s_0] \coloneqq 1$, if $s_0 = 0$, and 0 otherwise. For an introduce node i, we also add a +1 to the values of previously computed entries if $s_{t+1} = 0$ and the same conditions hold as in the counting version, while a value of 0 for invalid state-representations is substituted by an arbitrarily large negative value $-\infty$. For forget nodes i we now compare all previous partial solutions to retain the maximum over all states of the forgotten vertex, instead of computing their sum, while for join nodes, we also substituted by addition of entries from the previous tables (i.e. we move our computations from the sum-product ring to the max-sum semiring), as well as subtracting from each such computation the number of vertices of zero state for the given entry (that would be counted twice).

We next explain the necessary modifications to the exact algorithm for use of the rounded states $\sigma \in \Sigma_{\delta}^d$. Consider a node *i* introducing vertex v_{t+1} : for a new entry to describe a proper extension to some previously computed partial solution, if the new vertex is of state $s_{t+1} \in [1, d-1]$ in the new entry, then there must be some vertex $v_j \in X_i$, such that $s_{t+1} \leq d(v_{t+1}, v_j) + s_j$ (the one for which this sum is minimized), i.e. we require that the new state of the introduced vertex matches its distance to some other vertex in the bag plus the state of that vertex (being the one responsible for connecting v_{t+1} to the partial solution). The rounded state σ_{t+1} for v_{t+1} must then satisfy: $\sigma_{t+1} \leq d(v_{t+1}, v_j) \oplus \sigma_j$.

The rounded state σ_{t+1} for v_{t+1} must then satisfy: $\sigma_{t+1} \leq d(v_{t+1}, v_j) \oplus \sigma_j$. Further, states are now considered low if $0 < \sigma \leq \frac{\lfloor d/2 \rfloor}{(1+\epsilon)}$, while, from a set of already computed states σ' , the symmetrical (around d/2) state $\bar{\sigma}$ for a given low state σ is defined as the minimum state σ' for which $\sigma + \sigma' \geq \frac{d}{(1+\epsilon)}$. Thus, for a node introducing vertex v_{t+1} with state $\sigma_{t+1} = 0$, we require that $\forall v_j \in X_{i-1}$ with $\sigma_j = 0$, it is $d(v_{t+1}, v_j) \geq \frac{d}{(1+\epsilon)}$, and $\forall v_j \in X_{i-1}$ with $d(v_{t+1}, v_j) \leq \frac{\lfloor d/2 \rfloor}{(1+\epsilon)}$, it is $\sigma_j \leq d(v_{t+1}, v_j)$ and $\sigma' = \bar{\sigma}$ for $D_i[\sigma_0, \ldots, \sigma_{t+1}] \coloneqq D_{i-1}[\sigma'_0, \ldots, \sigma'_t] + 1$. Finally, for join nodes, we arbitrarily choose the computed states for the table of one of the children nodes to represent the new entries and again use $\bar{\sigma}$ to identify the symmetrical of each low state (from the other node's table).

Lemma 2. Given ϵ and a tree decomposition (\mathcal{X}, T) with $T = (I, F), \mathcal{X} = \{X_i | i \in I\}$, where T is rooted, binary and of depth $O(\log n)$, there exists a constant C, such that for all rounded states $\sigma_j \in \Sigma_{\delta}^d$, it is $\sigma_j \geq \frac{s_j}{(1+\epsilon)}, \forall v_j \in X_i, \forall i \in I$, where $\delta = \frac{\epsilon}{C \log n}$.

Proof. First, observe that for any rounded state σ calculated using the \oplus operator we have $\sigma \leq s$, where s is the state the exact algorithm would use instead. Let h be the maximum depth of the recursive computations of any state σ we may require. We now want to show by induction on h that it is always $\log_{1+\delta}(\frac{s}{\sigma}) \leq h$. For h = 1 and only one addition $\sigma = 0 \oplus d_1$, for some distance d_1 with $s = 0 + d_1$, we want $\log_{(1+\delta)}(\frac{s}{\sigma}) \leq 1$. It is indeed $\log_{(1+\delta)}(\frac{s}{\sigma}) = \log_{(1+\delta)}(d_1) - \lfloor \log_{(1+\delta)}(d_1) \rfloor \leq 1$.

For the inductive step, let $\sigma_3 = \sigma_2 \oplus d_2$ and $s_3 = s_2 + d_2$ be the final rounded and exact values (at depth h), for some distance d_2 and previous values σ_2, s_2 (for h - 1). It is $\log_{(1+\delta)}(\frac{s_3}{\sigma_3}) = \log_{(1+\delta)}(\frac{s_2+d_2}{(1+\delta)^{\lfloor \log_{(1+\delta)}(\sigma_2+d_2) \rfloor}}) = \log_{(1+\delta)}(s_2) + \log_{(1+\delta)}(1+\frac{d_2}{s_2}) - \lfloor \log_{(1+\delta)}(\sigma_2) + \log_{(1+\delta)}(1+\frac{d_2}{\sigma_2}) \rfloor$. This, after removal of the floor function, is $\leq \log_{(1+\delta)}(s_2) + \log_{(1+\delta)}(1+\frac{d_2}{s_2}) - (\log_{(1+\delta)}(\sigma_2) + \log_{(1+\delta)}(1+\frac{d_2}{\sigma_2})) + 1 = \log_{(1+\delta)}(s_2) - \log_{(1+\delta)}(\sigma_2) + \log_{(1+\delta)}(1+\frac{d_2}{s_2}) - \log_{(1+\delta)}(1+\frac{d_2}{s_2}) + 1$. The claim then follows, because $\log_{(1+\delta)}(s_2) - \log_{(1+\delta)}(\sigma_2) = \log_{(1+\delta)}(1+\frac{d_2}{\sigma_2}) \leq h - 1$ by the inductive hypothesis, while also $\log_{(1+\delta)}(1+\frac{d_2}{s_2}) - \log_{(1+\delta)}(1+\frac{d_2}{\sigma_2}) \leq 0$, as $\sigma_2 \leq s_2$.

Thus we have $\log_{(1+\delta)}(\frac{s}{\sigma}) \leq h$, from which we get $\frac{s}{\sigma} \leq (1+\delta)^h$. For $\sigma \geq \frac{s}{(1+\epsilon)}$, we require that $(1+\delta)^h \leq (1+\epsilon)$, or $h \leq \log_{(1+\delta)}(1+\epsilon) = \frac{\log_2(1+\epsilon)}{\log_2(1+\delta)}$, that gives $h \leq \frac{\epsilon}{\delta}$, for $\epsilon, \delta \approx 0$, or $\delta \leq \frac{\epsilon}{h}$. Next, observe that during the computations of the algorithm, the maximum depth h of any computation can only increase by one if some vertex is introduced in the tree decomposition, as paths to and from it become available. This means no inductive computation we require can be of depth larger than the depth of the tree decomposition T, giving $h = C \log n$ for some constant C.

Theorem 7. There is an algorithm which, given an edge-weighted instance of d-SCATTERED SET [G, k, d], a tree decomposition of G of width tw and a parameter $\epsilon > 0$, runs in time $O^*((tw/\epsilon)^{O(tw)})$ and finds a $d/(1 + \epsilon)$ -scattered set of size k, if a d-scattered set of the same size exists in G.

Proof. Naturally, our modified algorithm making use of these rounded values to represent the states will not perform the same computations as the exact version given in Section 4. The new statement of correctness, taking into account the approximate values now computed (and the switch to the maximization version), is the following:

$$\forall i \in I, \forall (\sigma_0, \dots, \sigma_t) \in (\Sigma_{\delta}^d)^{t+1}, 0 \le t < \text{tw}:$$
(13)

$$\left\{ D_i[\sigma_0, \dots, \sigma_t] = |K| : K \subseteq V_i \setminus X_i \cup \{ v_l \in X_i | \sigma_l = 0 \} :$$
 (14)

$$\{\forall u, w \in K : d(u, w) \ge \frac{d}{(1+\epsilon)}\} \land$$
(15)

$$\wedge \{ \forall v_j \in X_i | 0 < \sigma_j \le \frac{\lfloor d/2 \rfloor}{(1+\epsilon)}, \forall u, w \in K | d(u, v_j) \le d(w, v_j) :$$
(16)

$$d(u, v_j) \ge \sigma_j \wedge d(w, v_j) \ge \frac{d}{(1+\epsilon)} - \sigma_j \} \wedge \tag{17}$$

$$\wedge \{ \forall v_j \in X_i | \sigma_j > \frac{\lfloor d/2 \rfloor}{(1+\epsilon)}, \forall u \in K : d(u, v_j) \ge \sigma_j \} \lor$$

$$(18)$$

$$\forall D_i[\sigma_0, \dots, \sigma_t] = -\infty \big\}.$$
⁽¹⁹⁾

In words, the above states that for every node *i* and all possible stateconfigurations $(\sigma_0, \ldots, \sigma_t) \in (\Sigma_{\delta}^d)^{t+1}$ (13), table entry $D_i[\sigma_0, \ldots, \sigma_t]$ contains the size of a subset *K* of V_i (that includes vertices $v_l \in X_i$ of state $s_l = 0$) (14), such that the distance between every pair of vertices u, w in *K* is at least $d/(1 + \epsilon)$ (15), for every vertex $v_j \in X_i$ of low state $\sigma_j \leq \lfloor d/2 \rfloor/(1+\epsilon)$ and a pair of vertices u, w from K with u closer to v_j than w (16), its distance to u is at least equal to its state σ_j and its distance to w is at least $d/(1+\epsilon) - \sigma_j$ (17), while for every vertex $v_j \in X_i$ of high state $\sigma_j > \lfloor d/2 \rfloor/(1+\epsilon)$ and a vertex u from K, its state σ_j is at most its distance from any vertex u (18), or if there is no such K, we have $D_i[\sigma_0, \ldots, \sigma_t] = -\infty$ for this entry (19). This is shown by induction on the nodes $i \in I$:

- Leaf node *i* with $X_i = \{v_0\}$: This is the base case of our induction and the initializing values of 1 for $\sigma_0 = 0$ and 0 for $\sigma_0 > 0$ are indeed the correct sizes for *K*.
- Introduce node *i* with $X_i = X_{i-1} \cup \{v_{t+1}\}$: For entries with $0 < \sigma_j \leq \lfloor d/2 \rfloor/(1+\epsilon)$, validity of (15,18) is not affected, while for (16-17): it is $\sigma_{t+1} = \sigma_j \oplus d(v_{t+1}, v_j)$ for some vertex $v_j \in X_{i-1}$, for which, by the induction hypothesis we have that $\sigma_j \leq d(u, v_j)$ and $d(w, v_j) \geq d/(1+\epsilon) \sigma_j$, where *u* is the closest selection to v_j and *w* the second closest. To see the same holds for v_{t+1} , observe that $\sigma_{t+1} \leq d(v_{t+1}, v_j) + d(u, v_j) = d(u, v_{t+1})$ and $d(w, v_j) \geq d/(1+\epsilon) \sigma_j \Rightarrow \sigma_j + d(v_{t+1}, v_j) \geq d/(1+\epsilon) d(w, v_j) + d(v_{t+1}, v_j) \Rightarrow \sigma_j + d(v_{t+1}, v_j) \geq d/(1+\epsilon) d(w, v_{t+1})$. For entries with $\sigma_{t+1} \geq \lfloor d/2 \rfloor/(1+\epsilon)$, validity of (15-17) is not affected, while for (18): it is $\sigma_{t+1} \leq d(v_{t+1}, v_j) + \sigma_j$ for some $v_j \in X_{i-1}$, for which we have $\sigma_j \leq d(u, v_j)$ and thus also $\sigma_{t+1} \leq d(v_{t+1}, v_j) + d(v_j, u) = d(v_{t+1}, u)$.

For entries with $\sigma_{t+1} = 0$, observe that the low states σ_j of vertices $v_j \in X_{i-1}$ in the new entry with $d(v_{t+1}, v_j) \leq \lfloor d/2 \rfloor/(1 + \epsilon)$ would need to be $\sigma_j \leq d(v_{t+1}, v_j)$ and also correspond to the minimum high original state σ'_j such that $\sigma_j + \sigma'_j \geq d/(1 + \epsilon)$, for which partial solution it is $d(v_j, u) \geq \sigma'_j, \forall u \in K$ and thus $d(v_j, u) \geq d/(1 + \epsilon) - \sigma_j$ (16-17). For high states σ_j of vertices $v_j \in X_{i-1}$, it is $d(v_{t+1}, v_j) \geq \sigma_j$ (18) and finally, for (15), if there was some $u \in K$ such that $u \notin X_{i-}$ and $d(u, v_{t+1} < d/(1 + \epsilon)$, then there must be some $v_j \in X_{i-1}$ of new state σ_j and previous state σ'_j (on the path between u and v_{t+1}) for which $\sigma_j + \sigma'_j < d/(1 + \epsilon)$, contradicting the requirement for introduction of v_{t+1} with $\sigma_{t+1} = 0$: it is $d(u, v_{t+1}) < d/(1 + \epsilon) \Rightarrow d(u, v_j) + d(v_{t+1}, v_j) < d/(1 + \epsilon) \Rightarrow \sigma_j + \sigma'_j < d/(1 + \epsilon)$, as it must be $\sigma'_j \leq d(u, v_j)$ and also $\sigma_j \leq d(v_{t+1}, v_j)$.

- Forget node *i* with $X_i = X_{i-1} \setminus \{v_{t+1}\}$: No modification to the exact dynamic programming affects the correctness of (13-18), as, the right number is indeed the maximum over all states for v_{t+1} .
- Join node *i* with $X_i = X_{i-1} = X_{i-2}$: For (15), if there was a pair $u \in K \cap V_{i-1} \setminus X_{i-1}, w \in K \cap V_{i-2} \setminus X_{i-2}$ with $d(u,w) < d/(1+\epsilon)$, then there must be some vertex $v_j \in X_i$ (on the path between the two) for which $\sigma_j + \bar{\sigma_j} < d/(1+\epsilon)$ (as above). For (16-18), observe that for vertices of low state σ_j , lines (16-17) must have been true for either i-1 or i-2 and (18) for the other, while for vertices v_j of high state σ_j , it again suffices that (18) must have been true for both.

For a node $i \in I$, let $U_i(k, s_0, \ldots, s_t) = \{K \subseteq V_i | K \cap X_i = \{v_j \in X_i | s_j = 0\}\}$ be the set of all d-scattered sets in G_i of size k for this state-configuration $\begin{array}{l} (s_0,\ldots,s_t) \text{ (as in the proof of Theorem 2), } U_i(k,\sigma_0,\ldots,\sigma_t) = \{K \subseteq V_i | K \cap X_i = \{v_j \in X_i | \sigma_j = 0\} \text{ be the set of all subsets } K \text{ of } V_i \text{ of size } k \text{ for the rounded state-configuration } (\sigma_0,\ldots,\sigma_t) \text{ (computed by our approximation algorithm) and } U_i(k, \frac{s}{1+\epsilon}) \text{ be the set of all } d/(1+\epsilon)\text{-scattered sets of size } k \text{ in } G_i. \text{ Consider a set } K \in U_i(k,s_0,\ldots,s_t) \text{ and let } (\sigma_0,\ldots,\sigma_t) \text{ be the state-configuration resulting from rounding each } s_j \text{ down to its closest integer power of } (1+\delta), \text{ or } \sigma_j = (1+\delta)^{\lfloor \log_{(1+\delta)}(s_j) \rfloor}, \forall j \in [0,t]. \text{ As } |K| = k \text{ and for any pair } u, w \in K, \text{ we have } d(u,w) \geq d > \frac{d}{(1+\epsilon)}, \text{ we want to show that the requirements of } (\sigma_0,\ldots,\sigma_t) \text{ also hold for } K. \text{ By Lemma 2, we know that } s_j \geq \sigma_j \geq \frac{s_j}{(1+\epsilon)} \text{ for all } j \in [0,t]. \text{ Now, for each } \sigma_j \leq \lfloor \frac{d/2}{1+\epsilon}, \text{ then } \frac{s_j}{(1+\epsilon)} \leq \lfloor \frac{d/2}{(1+\epsilon)} \text{ and } s_j \leq \lfloor d/2 \rfloor \text{ (i.e. } s_j \text{ is also low)} \text{ and we have that } d-s_j \leq d(w,v_j) \text{ for } w \in K \text{ being the second closest to } v_j, \text{ form which we get } \frac{d}{(1+\epsilon)} - \frac{s_j}{(1+\epsilon)} \leq \frac{d(w,v_j)}{(1+\epsilon)} \Rightarrow \frac{d}{(1+\epsilon)} - \sigma_j \leq \frac{d(w,v_j)}{(1+\epsilon)} \leq d(w,v_j), \text{ i.e. state-configuration } (\sigma_0,\ldots,\sigma_t) \text{ also holds for set } K. \text{ This means } K \in U_i(k,\sigma_0,\ldots,\sigma_t) \text{ and thus we have } U_i(k,s_0,\ldots,s_t) \subseteq U_i(k,\sigma_0,\ldots,\sigma_t). \text{ Further, since for any } K \text{ our approximation algorithm will compute, it is } d(u,w) \geq d/(1+\epsilon), \forall u,w \in K, \text{ we also have } U_i(\sigma_0,\ldots,\sigma_t) \subseteq U_i(k,\frac{s}{(1+\epsilon)}). \text{ Due to these considerations, if a d-scattered set of size k exists in G, our algorithm will be able to return a set K \text{ with } |K| = k, \text{ that will be a } d/(1+\epsilon)-scattered set of G. \end{array}$

The algorithm is then the following: first, according to the statement of Lemma 2, we select $\delta = \frac{\epsilon}{C \log n}$, that we use to define set Σ_{δ}^{d} and then we use the algorithm of Theorem 2, modified as described above, on the bounded-height transformation of nice tree decomposition (\mathcal{X}, T) . Correctness of the algorithm and justification of the approximation bound are given above, while the running time crucially depends on the size of Σ_{δ}^{d} being $|\Sigma_{\delta}^{d}| = O(\log_{(1+\delta)} d) = O(\frac{\log d}{\log(1+\delta)}) = O(\frac{\log d}{\delta})$, where we used the approximation $\log(1 + \delta) \approx \delta$ for sufficiently small δ (i.e. sufficiently large n). This gives $O(\log n/\epsilon)^{O(tw)}$ and the statement is then implied by Lemma 3.

As a final note, observe that due to the use of the $|\cdot|$ function in the definition of our \oplus operator, all our values will be rounded *down*, in contrast to the original version of the technique (from [24]), where depending on a randomly chosen number ρ , the values could be rounded either down or up. This means there will be some value x, such that $x \oplus 1 = x$, or $(1 + \delta)^x = (1 + \delta)^{\lfloor \log_{(1+\delta)}(x+1) \rfloor}$ (we would have $x \approx 1/\delta$). One may be tempted to conceive of a pathological instance consisting of a long path on n vertices and d >> x, along with a simple path decomposition for it (that is essentially of the same structure), where the computations for each rounded state σ would "get stuck" at this value x. In fact, the transformation of [6] would give a tree decomposition of height $O(\log n)$ for this instance, whose structure would be the following: the leaf nodes would correspond to one vertex of the path each, while at (roughly) each height level i, sub-paths of length 2^i would be joined together. Thus each join node t that corresponds to some sub-path of length 2^i (let $X_t = \{a, b, c, d\}$) would have two child branches, consisting of two forget nodes, two introduce nodes and a previous join node on each side (let these be t - 1, t - 2), computing sub-paths of length

 2^{i-1} (with $X_{t-1} = \{a, a', b', b\}$ and $X_{t-2} = \{c, c', d', d\}$). The vertices forgotten at each branch would be the middle vertices of the sub-path of length 2^{i-1} already computed at the previous join node of this branch (i.e. a', b' for the t-1 side and c', d' for the other), while the introduced vertices would be the endpoints of the sub-path of length 2^{i-1} computed at the other branch attached to this join node (i.e. c, d for the t-1 side and a, b for the other). In this way, in each branch (and partial solution) there will be one vertex (c or b) for which the rounded state would need to be $\leq 1 \oplus$ the rounded state σ of some neighbor (b or c) and one vertex (d or a) for which the \oplus operator would be applied between the state σ of some non-adjacent vertex (a, b or c for the t - 1 side and c, d or b for the other)and their distance (e.g. d(b, d) and d(c, a)), these being at least 2^{i-1} . In this way, the algorithm will not have to compute any series of rounded states sequentially by $\oplus 1$ and as, by Lemma 2, we have that for all nodes $i \in I$ and vertices $v_j \in X_i$, it is $\sigma_j \geq \frac{s_j}{(1+\epsilon)}$, for all $\sigma_j \in \Sigma^d_{\delta}$, the rounded states used by the algorithm for these introduce/join nodes will never be more than a factor of $(1 + \epsilon)$ from the ones used by the exact algorithm on the same tree decomposition.
